THE author's aim in this book is to bring together in a concise and readable form the facts and considerations upon which modern pathology rests, and to treat pathological processes as expressions of physico-chemical laws, not in terms of the older conceptions of use, harm, defence, vital forces, conscious purposes, and so forth. Further, wherever possible he has attempted to present modern ideas in a rational manner by tracing their historical development, since, as he justly claims, the history of science, the bearing and influence which one step of thought exerts upon the next, is of real educational value. This is an ambitious programme and a difficult one to carry out in a book of some hundred thousand words. Unfortunately, the author's style is not suited to conditions which demand that one sentence shall do the work of three. He is compelled to resort to a liberal use of brackets—in one place no less than six occur in eight consecutive lines, and many adjectives; and there is nothing more inept than the ill-chosen adjective. What conception of the plasma cell, for example, is the student likely to get when he is told that it has "smooth, supple protoplasm"? And how likely is he to recognise an actinomycotic lesion on the strength of the information that "the centre exhibits the characteristic radiating, often club-shaped, filamentous convolutions"? Such descriptive lapses might have been mitigated by illustrations, but there are none. Nor do we think the author has discriminated wisely in the amount of space he has allotted to the various divisions of this subject. While one-third of the book is devoted to elementary bacteriology, other subjects are dealt with in the most superficial way, and what may be called functional pathology is scarcely mentioned.

If the general arrangement and presentation of the subject are open to criticism, so is the standard and even the accuracy of the teaching. The chapter on the pathogenic protozoa contains no reference to the Sarcodina, although it includes a subsection on the filterable viruses. But on page 47 we read "there exist a number of infective organisms in relation to dysentery, some of which are not even bacteria, but protozoa. Since the discovery of the ameba coli by Koch and Kartulis in Egypt, which was later confirmed by Osler, Councilman and Lafleur, and others, amebic dysentery has come to be recognised as a tropical disease." Such an error as this is unpardonable in any text-book, however elementary.

The chapter on immunity is interesting and the author has the courage to discard old shibboleths, but we are surprised to find that his researches lead him to the conclusion that blood for the Wassermann test must be drawn directly from vessels and never taken after a meal, during a fever, during any acute infectious disease, during suppurations, including ulcerating or necrosing tumours, and after narcosis. Surely this teaching is directly opposed to experience. The section dealing with the degenerations is adequate if not profound, and the same may be said for the treatment of inflammation. The section on tumours is not well done. The nomenclature employed is often unfortunate; it is quite unnecessary to call a fibrosarcoma a fibroma sarcomatodes, and the use of the word organoid to describe the epithelial neoplasm has nothing to recommend it; a carcinoma is a dreadful thing at any time, but it becomes unspeakably bad when it is described as an "undifferentiated, immature, uncoördinated, generalising organoid tumour." One of the most important fields of research in the pathology of human cancer is the separation of the blastomatoid processes from the true neoplasms, but this aspect of the subject is not touched upon; and in the subsection on metastasis, instead of the modern doctrines of permeation, we have vague generalisations about tissues of selection and the preparation of soils for metastases by inflammation and degeneration, "which occurs frequently in the neighbourhood of tumours, especially in the regional lymph glands into which tumour products drain concentrated products."

We can see no reason why Professor Oertel's book should supersede any of the text-books on general pathology now in use.

NEUROLOGY.

Traumatismes Cranio-Cérébraux. Accidents Primitifs, leurs Grands Syndromes. By H. DURET, ex-Chirurgien des Hôpitaux de Paris. Paris: Librairie Felix Alcan. 1921. In two volumes. Vol. II., Parts 1 and 2. Pp. 1356. Fr.150.

IN this monumental book the veteran Dr. Duret, whose initial work on a subject he has made peculiarly his own dates back more than 40 years, has tackled in comprehensive fashion injury to the head, and its sequelæ. The first volume (not now under review) dealt with cranial fractures; the second, divided into two sub-volumes of 1300 pages, is concerned with the rôle of the cerebro-spinal fluid as a compensating and regulating agent, and with commotio cerebralis, which is reviewed and re-examined from every standpoint. Here is a mine of information from which material of value will be extracted for many years to come.

In the great majority of cases of external violence to the head the force applied to the cranial cupola divides itself into two parts; one spends itself in vain against the solid resistance of the head coverings, the difficult to convert a mild diabetic dog into a severe one by overfeeding with proteins. These experiments seemed to show that the practice of keeping carbohydrates very low was the right one. Allen had well said that the patient should order his life according to the size of his pancreas. Dr. Graham would prefer to say, according to the number and the health of the islands of Langerhans in the pancreas, since it had been shown by the work of Bensley and of Allen that the islands of Langerhans had specific granules and are intimately connected with carbohydrate metabolism.

"Pancreatic," "Hepatic," and "Concurrent" Curves.

Dr. P. J. CAMMIDGE said that the modern "fasting" treatment of diabetes was undoubtedly a great advance on any previous form of treatment. But it demanded considerable will power from the patient, who, in many cases, had only a bare subsistence diet. Of 143 cases treated by Dr. Cammidge by this method 52 had died, giving a mortality of 36 per cent. In some cases the treatment gave rise to disquieting symptoms from an early stage. Rapidly increasing acidosis has been reported by Allen, and Dr. Cammidge had also met with nervous disturbances—ataxia, tetanic convulsions, and pronounced œdema—which necessitated abandonment of the treatment. Allen's treatment was based upon experiments on partially depancreatised dogs, and it was assumed that the results of these experiments could be applied to diabetes in man. It was, however, only possible to demonstrate pancreatic disease post mortem in a small proportion of cases of diabetes. It must be remembered that fasting treatment gave physiological rest to other organs besides the pancreas and without some new method of testing it was impossible to decide whether Allen's hypothesis was correct. Dr. Cammidge believed that we now had such a method. This depended upon determination of the difference (called the "difference value") between the percentage of sugar and the percentage of total carbohydrates in a series of samples of blood taken before and after a test breakfast of known composition. The "difference value" in health did not exceed 0·006 per cent. fasting; as the blood-sugar rose after breakfast the "difference value" might fall slightly, to rise again as the percentage of sugar in the blood diminished. It should never exceed 0·01 per cent. In a partially depancreatised dog the fasting "difference value" was always abnormally high. After a mixed meal it fell for several hours while the blood-sugar curve rose. A similar relation between the blood-sugar and "difference value" curves was found to occur in cases of pancreatitis in man. Dr. Cammidge therefore thought that the method when applied to diabetes might help in deciding whether the disease was or was not due to pancreatic lesions. A few of the cases tested gave typical opposed or "pancreatic" curves, but others showed a different type of curve which could be reproduced in animals by interference with the functions of the liver, and which Dr. Cammidge therefore termed the hepatic type of curve. There was a third ("concurrent") type of curve which was still being investigated.

Of 140 cases of diabetes investigated by this method, 45 showed "pancreatic" curves, 48 "hepatic" curves, and 31 "concurrent" curves. It would therefore appear that clinical diabetes was not a simple entity, but a symptom complex which might develop along at least three lines of which disturbance of the pancreas was only one. We could now understand why no one system of treatment would yield uniformly satisfactory results in all cases: the fasting treatment most nearly attained a satisfactory result probably because it secured physiological rest for other organs besides the pancreas. Dr. Cammidge had found that the pancreatic type exhibited rapid improvement, whereas the hepatic type did not do so well under the fasting treatment, and, indeed, was apt to develop serious acidosis. Further experiment suggested that patients of the latter type were peculiarly sensitive to fats and protein, while they could tolerate a diet relatively rich in carbohydrate, and particularly in dextrinised starch. These were the patients who derived benefit from the Van Noorden oatmeal cure. Dr. Cammidge himself thought the large amount of fat advised by Van Noorden to be a mistake. By means of a modified oatmeal diet and a judicious arrangement of semi-fast or vegetable days, he found it possible to bring about a great improvement in these cases. Acidosis rapidly cleared up, and the sugar content of the blood could gradually be brought within normal limits.

Dr. F. J. POYNTON spoke of the disappointing results of the dietetic treatment of children under 8 suffering from diabetes. Even if the children remained sugar-free for months they seemed to relapse; and each time they relapsed it was more difficult to get them sugar-free. Dr. Poynton felt that we must look further than elaborate dieting for a real cure of diabetes.

The PRESIDENT said that no points of a very contentious nature had been raised in the interesting discussion, and he would therefore not call upon the opener to reply.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OTOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Oct. 21st, with the new President, Dr. LOGAN TURNER (Edinburgh), in the chair.

The Structural Type of the Mastoid Process.

Dr. Turner chose as the subject of his Presidential address the Structural Type of the Mastoid Process, based upon the skiagraphic examination of 1000 crania of various races of mankind. The contribution was profusely illustrated, and table summaries of cases were presented. It was preceded by general remarks on the position of the specialty. The President said the prestige of otology in this country lay largely in the hands of the members of that section, and that in the summer of next year an international meeting in Paris was promised. Many problems still remained for solution, and he urged younger members of the department to concentrate upon some particular piece of scientific investigation which would reflect credit on themselves and give added kudos to the position of otology in the country. The recent inauguration of a department of literary research by the American College of Surgeons was a movement which must appeal to members. Fifteen years ago Dr. Turner himself commenced issuing reports as departmental surgeon, and had ever since published a statistical survey of the work done.

Turning to the special subject of his address, he said the application of radiology to the study of the mastoid process on an extensive scale had not hitherto received the attention of anatomists, though Beck, of Chicago, had examined many in this way. The present research had been made into the skulls of men of a number of races, giving to it an anthropological interest. He commenced the study in 1913, in association with the late Major W. G. Porter, D.S.O., and shortly before the war Dr. Porter had radiographed 2000 temporal bones in 1000 crania. The following were the anatomical points inquired into: (*a*) relative frequency of occurrence of the two types of mastoid process; (*b*) the symmetry and asymmetry of the mastoid types; (*c*) the types and their asymmetry in the two sexes. On the anthropological side the inquiry had been made into the relative frequency of the two types of mastoid process in dolichocephalic, mesaticephalic, and brachycephalic crania; the mastoid types as they occurred in pure and mixed races; the development of the mastoid and frontal air-spaces in crania of a similar cephalic index and in the skulls of the same races of men. The infantile and pneumatic types of mastoid could be devoted to the leucocytic formula, biological investigation and bacteriological and parasitic examination, while the concluding chapter of this part of the book deals with the most recent methods of research such as Lange's colloidal gold reaction, elaborated by Miller and Levy and by Lowrey, Smith's mastic reaction, Szeci's oxidase reaction, and the Weil-Kafka hæmolysin test.

The third and fourth parts of the work consist of details of 177 cases, comprising 206 analyses. Those dealt with are syphilis, tabes, general paralysis, tuberculous meningitis, non-tuberculous meningitis, meningismus, exanthemic typhus, meningeal hæmorrhage, hemiplegia, myelitis, polyneuritis, cerebral tumour, various other organic nerve lesions, neurosis, various diseases other than those of the nervous system, and Bright's disease. The fifth part is a description of the technique employed by the author in carrying out the various investigations. The most noteworthy points in his conclusions may be summed up as follows: The average quantity of urea was 0·2 against 0·06 calculated by Mestrezat; Noguchi's reaction when negative excludes syphilis, when positive gives an indication in favour of syphilis if the amount of albumin is normal or only slightly raised; the existence of meningitis without cellular reaction is not admitted, unless in exceptional cases of localised meningitis, a conclusion contrary to the views of various observers, among them being Anglada and Mestrezat; leucocytosis is much more frequent than is supposed, even in atypical affections of the central nervous system. During generalised syphilis, even before secondary symptoms have arisen, modifications in the fluid were frequently met with, especially excess of albumin, lymphocytosis, and even a positive Wassermann, and syphilitic epilepsy was more common than is supposed. It was found that the W.R. was always positive in general paralysis; also that a marked lowering of the percentage of chlorides was an almost certain indication of tuberculous meningitis.

The work is completed by an extensive bibliography, in which we note the names of Graham Forbes, Lowrey, Miller and Levy, and Louis Weed. A systematic treatise on the cerebro-spinal fluid such as this supplies a want and constitutes a valuable text-book of reference both for the clinician and the pathologist. Prof. Pereira's book is a monument of arduous work and intelligent research summarised in a useful and complete form.

LABORATORIES: THEIR PLANNING AND FITTINGS.

By A. E. MUNBY. London: G. Bell and Sons. 1921. Pp. 220. 25*s.*

THE excellence of the work done in laboratories depends a great deal more on the people who use them than on the building and fitments. But it is no doubt easier to do good work in convenient and well-equipped institutes than in such places as Claude Bernard had, and it is not invariably true that the building of a new laboratory is the last work of every fertile investigator to whose duties this exacting task is added. Anyone who has to undertake the job will find many useful hints in Mr. Munby's book; anyone who has actually done it will find some points of disagreement and some of omission. The design and especially the internal arrangement of laboratories naturally reflect the individuality which is characteristic of laboratory workers, and no one could think of standardised laboratories without having visions of standardised brains. On some general points, however, advice is very useful, especially to those who may not have had much opportunity of seeing a diversity of institutions.

The book is arranged in the main under subjects—physics, chemistry, and biology with a specially good chapter on "laboratory services"—and this is perhaps rather an objection, since it obscures the sound principle that laboratories should be capable of being used for almost any purpose. What is wanted, shortly, is a good firm building, the shell of which will stand by itself, with the internal divisions on each floor constructed in such a way that they can be easily remodelled for changing requirements; as many windows and as large as can be secured; abundance of gas, water, electric current and drains, with adequate arrangements for heating and fume cupboards; standardised blocks of drawers and cupboards on which bench tops can be arranged as required. These are the essentials which require attention before the building is begun; and on this foundation almost any sort of specialised work can be accommodated. There are 165 useful plans and pictures and an interesting historical introduction on early laboratories by Sir Arthur Shipley.

CHEMISTRY.

Introduction to Qualitative Analysis. By TH. WILHELM FRESENIUS. Seventeenth edition of the original work by C. R. FRESENIUS. Translated by C. A. MITCHELL, M.A., F.I.C. London: J. and A. Churchill. 1921. Pp. 954. 36*s.*

THE original German edition of this standard work appeared as far back as 1840 and the present volume has been remodelled to make it conform with the modern conceptions of chemistry. Part I. is concerned with the general principles and methods of analytical chemistry and Part II. with a systematic course of qualitative chemical analysis. The author rightly insists that to conduct qualitative investigations it is necessary to have a knowledge of the chemical elements and their most important compounds, and also of the fundamental laws of chemistry, whilst practice in the visualisation of chemical processes is also essential. If to manipulative skill is added the practice "when results contrary to experience are obtained of looking for an error in the experiment itself, or rather in the absence of a condition necessary for the production of the phenomenon, since this habit must be based on a firm belief in the unsuitability of the laws of nature, then all the conditions necessary for a fruitful study of analytical chemistry are present." These words are worth the quoting since they express the ideals of a great master of analytical chemistry.

The portion of the work dealing with the examination of natural waters and the detection of poisonous elements is well up to date and will enhance the value of this recognised standard work to the medical profession. Mr. Mitchell has carried out a difficult task well, and it is obvious that the greatest care has been taken in the rearrangement and translation.

Dictionary of Applied Chemistry. Vol. II. By Sir EDWARD THORPE, C.B., LL.D., F.R.S. London: Longmans, Green and Co. 1921. Pp. 717. 60*s.*

VOL. II. of this important work, which starts with "Calculi" and ends with "Explosion," follows with commendable rapidity on Vol. I. Many of the articles will be read with great interest by medical men. The section on carbohydrates, contributed by Dr. E. F. Armstrong, F.R.S., is an admirable survey of the properties and occurrence of these important compounds. Under the heading of dextrin it is stated that maltodextrin $6(C_6H_{10}O_5)H_2O$ is the only dextrin which has been prepared in anything like a state of purity; we may point out that Mr. J. L. Baker in 1902 described the preparation and properties of α-amylodextrin which is quite a well-defined compound. The section on cellulose is written by the well-known authority, Mr. C. F. Cross, F.R.S., and is worth reading by those who are interested in this subject. The manufacture and properties of chloroform are described by Dr. A. J. Ewins, who points out the need of especial care in the manufacture of chloroform for anæsthetic purposes. The presence of small amounts of impurities has a deleterious and often dangerous influence, and many cases of death under chloroform have been attributed to the employment of impure anæsthetic. The effect of alcohol as a preservative of chloroform is

SOCIETY OF M.O.'S OF INFANT WELFARE CENTRES AND SOCIETY OF M.O.H.

A JOINT meeting of these societies was held at University College, London, on Oct. 20th, with Dr. H. C. CAMERON in the chair.

Dr. CAMERON, representing the Society of Medical Officers of Infant Welfare Centres, presented the report of the subcommittee recommending amalgamation of this Society with the Society of Medical Officers of Health.

Prof. H. R. KENWOOD, representing the latter Society, supported the adoption of the report. His Society, he said, was becoming very representative, including all those engaged in public health work of any kind. It was at that moment contemplating the formation of a section for maternity and child welfare. Each of its groups was autonomous except for questions of general policy. The groups had a one-third representation on the Council; groups were already formed all over the country. The Society of M.O.H. would welcome amalgamation with the Society of M.O.'s of Infant Welfare Centres. All members of the latter, whether working for municipal or voluntary centres, would be eligible.

Dr. A. B. MCMASTER proposed and Dr. H. RONALD CARTER seconded the adoption of the report, and this was carried unanimously.

The committee of the newly-formed group of the Society of M.O.H. was then elected with power to appoint its own officers.

Dr. CAMERON then read a paper on

The Nature of Summer Diarrhœa.

He maintained that the usual belief that summer diarrhœa was due to an organism conveyed in milk, communicated directly from child to child and disseminated by the house-fly, was not proved. Heat was said to act indirectly by encouraging the bacterial decomposition of milk. The weight of evidence, in his opinion, went rather to prove that it was due to the direct action of heat on the unstable heat centre of the infant. It was admitted by all that contamination of milk with streptococci or other pathogenic organisms is capable of producing epidemics of diarrhœa; but that the mere multiplication of the usual milk saprophytes could produce diarrhœa Dr. Cameron maintained that we had no evidence. In spite of present-day methods of milk sterilisation the dangers and difficulties of the artificial feeding of infants were still with us. Infants fed on the breast, cow's milk, dried and condensed milks and proprietary foods were alike affected. The mortality of infantile diarrhœa resulted from several types of disease all favoured or caused by persistently high temperature. Dr. Cameron described the effect of the latter upon infants and concluded that the great summer mortality was not entirely or chiefly due to infective enteritis, the result of the contamination of the milk-supply, but was to be attributed to the prejudicial effect of heat (1) in lowering the need for food and the tolerance for food, (2) in diminishing the force and activity of the digestive secretions, (3) in encouraging the overgrowth and migration of bacteria, which are normal inhabitants of the colon, in other parts of the bowel. He divided summer diarrhœa into four groups: (*a*) group showing some disturbance of the heat-regulating mechanism together with digestive disturbances of greater or less severity; (*b*) a group comprising cases of acute catarrhal or follicular colitis and a few in which the bacilli of dysentery have been found; (*c*) a group of cases of "heat stroke" in which cerebro-spinal symptoms are the most prominent; (*d*) a terminal state of "intoxication," the very characteristic symptoms of which are evident in almost all cases before death. Preventive propaganda at present assumed the infective nature of the disease. It was possible that measures to assist the young child to combat the direct influence of heat would be more fruitful of results.

Dr. Cameron concluded by picturing the infant enveloped in many layers of impervious flannelette, lying on a feather bed in the most airless corner of an airless room, crowded with adults, and opening only upon a court-yard in which the temperature is 90°F. in the shade; an infant whose restlessness and crying and thirst is soothed by the free administration of an artificial diet. He maintained that such an infant is under conditions peculiarly well fitted to produce the disturbance of body temperature which leads to a loss of all tolerance to food, and to ultimate intoxication from bacterial overgrowth and endogenous infection. To urge the overwrought mothers of such an infant to practise rigid cleanliness in the handling of the milk or to demand a low bacterial count of milk saprophytes per cubic millimetre in the milk were measures not in themselves sufficient.

Discussion.

Dr. E. H. T. NASH compared the summers of 1898, 1911, and 1921, all of them intensely hot. In 1898 and 1911 terrific epidemics of summer diarrhœa occurred, but this year although the heat and drought had been greater than ever, nothing like a serious outbreak had occurred. He maintained, therefore, that heat was not the most important factor. Was the change due to the introduction of dried milk?

Prof. T. E. HILL suggested that the change was due primarily to the education of the mother through the infant welfare movement, and partly also to the replacement of the privy system by the water-carriage system of drainage.

Dr. H. SCURFIELD said that Dr. Cameron's idea received support from the fact that mothers had now been taught to put their infants to sleep out of doors.

Dr. CAMERON, in reply, agreed that infant welfare work had been the most important factor in reducing infantile diarrhœa, but thought the result to have been achieved rather by educating mothers in rational clothing and other methods of combating the effects of heat than by the careful preparation of feeds.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—The first evening meeting of the present session will be held in the Society's lecture theatre at 17, Bloomsbury-square, London, W.C., on Nov. 9th, 1921, at 8 P.M., when Prof. W. E. Dixon, F.R.S., will read a paper on the Drug Habit. Medical friends of members and student-associates will be welcomed.

YORK MEDICAL SOCIETY.—At the indugural meeting of the session of the Society, held in the Tempest Anderson Hall at the Museum, York, on Oct. 19th, Prof. T. Wardrop Griffith delivered an address in which he discussed the future of the voluntary hospitals. The financial conditions affecting these institutions, the policy guiding the destinies of the Poor-law infirmaries, and the degree of intelligent generosity of the public of Yorkshire, made up, he said, an equation with as many unknown terms as there were considerations. If voluntary hospitals were taken over by the State or by municipal or Poor-law authorities, the cessation of private benevolence would necessitate increased taxation or rates; a hospital allotted to a stated area would lose its county reputation; the staff would cease to be honorary, and the question would arise of the comparative merits of full-time and part-time staffs. He was inclined to think that the service of part-time men—who were paid a moderate salary and were allowed to do private consulting practice—was the most likely form of service for hospitals of the future. He did not agree with Dr. Addison that the voluntary and municipal hospitals might go on for many years together; the former would be starved of pecuniary support and of suitable staffs as, unless he was greatly mistaken, was going to happen at Bradford. In conclusion, Prof. Griffith sketched his idea of the way in which the hospital system of the country might best be worked. In this system the present Poor-law infirmaries, with improved equipment, would be manned by a visiting staff of paid part-time officers, some of them young men fresh from the universities and medical schools, desirous of specialising or becoming consultants; whilst the voluntary hospitals, substantially subsidised by the State, would yet retain their freedom. An arrangement might be made by which those who benefited should pay, if they could afford it, for their maintenance in hospital, without loss of the truly voluntary character of the institution; in this way such patients would still be able to command the eager services of the best men in the profession.

to prevent clotting is a function of the amount of thrombin present, and the quantity required to prevent the serozyme-cytozyme combination is proportionate to the relative concentrations of these two substances in any given experiment. The author also considers that hirudin can exert an influence at a yet earlier stage, and inhibit the transformation of proserozyme into serozyme. Thrombin and antithrombin form an inert complex, the antithrombin being neutralised but not destroyed: heating will destroy the thrombin and set free the antithrombin again. The paper finishes with a quite interesting comparison between the action of thrombin and antithrombin in the presence of fibrinogen, and of toxin and antitoxin in the presence of the cell.—This number also contains a short paper by H. Limousin on the direct cultivation of *B. tuberculosis* from the sputum on Pétrof's medium, which has given the author satisfactory results.

Reports and Analytical Records

"VALEDA" INVALID FOOD AND "GOOD AS GOLD" BABY FOOD.

(AUSTEN FOODS, LTD., BATH.)

THESE two foods when analysed gave the following results:—

	"Valeda" per cent.		"Good as Gold" per cent.
Carbohydrates, starch, &c. ..	78·0	....	75·6
Fibre	0·6	....	0·5
Protein	12·1	....	11·1
Fat	1·5	....	1·4
Mineral matter	0·9	....	0·8
Moisture	6·8	....	10·6
	99·9	....	100·0
Matters soluble in cold water	6·3	....	5·8
Alkalinity (as $NaHCO_3$) ..	0·17	....	0·17
Starch liquefying enzyme ..	absent	....	absent
Nature of starch	wheat	....	wheat

These figures are characteristic of "heated flour" preparations. Nothing can be said against "Valeda" as an invalid food. With regard, however, to the infant's food, the words of Dr. F. J. H. Coutts in his report to the Local Government Board[1] may be quoted:

> "I am of opinion that foods containing unchanged starch or starch altered only by heating should not be given to babies under 7 months of age, except on the advice of, and under the supervision of, a medical man."

"ASEPSO" SOAP.

(MESSRS. EDWARD COOK AND CO., LTD., BOW, LONDON.)

This soap is stated to be a remedy for eczema, ringworm, and other skin troubles. When analysed it was found to contain 2·8 per cent. of mercuric iodide (HgI_2), which confirms the manufacturers' claim of 3 per cent. of this ingredient. The germicidal value of mercuric iodide is well known, and it is obvious that this soap, used with discretion, should be of considerable value to the medical practitioner.

LYND'S "WELL-MADE" SOAP.

(WM. LYND AND CO., BOWMAN-LANE SOAP WORKS, LEEDS.)

We have received a sample of soap of the "Well-made" brand for examination. Our analysis showed the following percentage composition:—

Water	27·07	per cent.
Fatty anhydrides	61·48	"
Free alkali as NaOH	0·01	"
Alkali (Na_2O) combined as sodium carbonate	0·64	"
Alkali (Na_2O) combined as soap..	6·87	"
Insoluble matter	0·10	"
Resin acids	present.	

This soap is of good quality and suited for domestic purposes. The amount of free alkali and insoluble matter is negligible.

VERMOUTH, FRATELLI CORELLI, TORINO.

(EDWARD YOUNG AND CO., LTD., 62–3, MARK-LANE, LONDON, E.C. 3.)

On analysis this vermouth was found to have the following composition:—

Alcohol (by weight)	11·34	per cent.
Fixed acidity (as tartaric).. ..	0·36	"
Volatile acidity (as acetic)	0·06	"
Extract	15·26	"
Total sugars	14·70	"
Specific gravity		1011·72°

This vermouth consists of a matured wine to which has been added certain vegetable extracts, mostly derived from the cinchona family. The analytical results quoted above are typical of a good vermouth. Skilful blending of the flavouring matters has resulted in a very palatable product, which is free from "harshness" or excessive sweetness.

WILBERT'S INVALID PORT.

(WILLIAMS, HUMBERT, AND CO., 38, MINCING-LANE, E.C.)

When drawn from bond and analysed this wine was found to have the composition:—

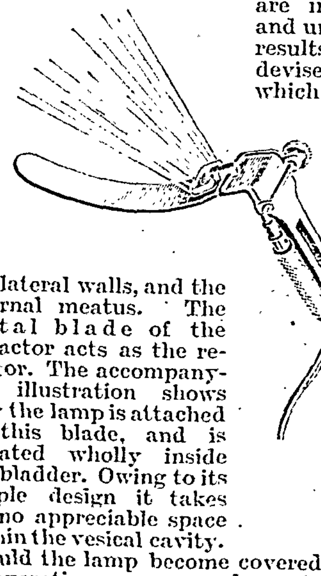
Alcohol	21·3	per cent. (by volume)	
equivalent to	37·3	"	proof spirit.
Total extractives	9·4	"	
Containing—Mineral matters	0·2	"	
" sugars ..	8·5	"	
Total acidity (tartaric) ..	0·33	"	
Volatile acidity (acetic) ..	0·03	"	

The sugars consist of a mixture of dextrose and lævulose, cane sugar being absent. The analytical results confirm the statement of the vendors that this is a straight Douro port wine containing no admixtures.

New Inventions.

A NEW BLADDER LAMP.

THE method commonly in use for the artificial illumination of the interior of the bladder during an open operation is to reflect electric light from either a hand- or head-lamp through the opening made in the anterior abdominal wall. Both these lamps are inconvenient to use and unsatisfactory in their results. Recently I have devised an electric lamp which can be fitted to the posterior blade of Thomson Walker's bladder retractor. It completely illuminates the base of the bladder, the lateral walls, and the internal meatus. The metal blade of the retractor acts as the reflector. The accompanying illustration shows how the lamp is attached to this blade, and is situated wholly inside the bladder. Owing to its simple design it takes up no appreciable space within the vesical cavity. Should the lamp become covered with blood during an operation a gauze swab on forceps will efficiently clean it. The lamp with its attachment can be sterilised by insertion in methylated spirit or 1 in 40 carbolic acid. During the operation the cable lies beneath a sterilised towel and does not come in contact with any instrument.



The lamp can be obtained from the Genito-Urinary Manufacturing Company, to whom I desire to express my thanks for much valuable help in its design.

Welbeck-st., W. CLIFFORD MORSON, O.B.E., F.R.C.S.

other originates within the skull an active secondary force, universally known as commotion, which is transmitted in all directions by the incompressible cerebro-spinal fluid. Hence result all grades of traumatic lesion of the neuraxis, described by the author with profusion of detail, ranging from hæmorrhages and contusions to molecular disturbances. Some attention is paid to the curious cases of death, without obvious objective findings, consecutive to trauma, and the author is convinced that more minute investigation, especially of the medulla, would in such cases reveal adequate cellular or other modification. The volumes are well illustrated, personal and other cases are cited copiously, and while many of the bibliographical references date back to the latter half of last century recent work derived from war experiences is by no means ignored. It is somewhat tiring to the eye to encounter everywhere in the book a most prodigal use of italics and of capitals, and, as too commonly still the case with French scientific volumes, an index is wanting, for which lack a *table des matières* in no way compensates.

Leitfaden der Neurologischen Diagnostik. Eine Differentialdiagnose aus dem führenden Symptom für praktische Aerzte und Studierende. By Dr. KURT SINGER. Berlin and Vienna: Urban and Schwarzenberg. 1921. With 33 illustrations. Pp. 201.

Dr. Singer's little guide to neurological diagnosis is based on the principle that for the general practitioner it is unnecessary to be able to differentiate between, say, Friedreich's disease and hereditary cerebellar ataxia, whereas he ought to be in a position, recognising the main symptoms of nervous cases, to determine their localising or diagnostic import. Rigorous exclusion of non-essentials has enabled the author to produce a book suitable for the needs of the busy practising physician arranged under such headings as paralysis, amyotrophy, disorders of sensibility, gait, twitching, cramps or fits, tremors, neuralgia, headache, giddiness, &c. Only a sound and wide knowledge on the author's part has enabled him to pack so much information into so little space. The book appears well calculated to fulfil its mission.

THE DIRECTION OF HUMAN EVOLUTION.

By E. G. CONKLIN, Professor of Biology in Princeton University. London: Humphrey Milford. 1921. Pp. 247. 12*s.* 6*d.*

THE lectures which go to form this interesting volume were given under the John Calvin McNair lectureship in the University of North Carolina "on the mutual bearings of science and religion upon each other." In the first part, on the paths and possibilities of human evolution, the author examines the past history of man for indications of his future. He concludes that there is no probability that a higher animal than man will ever appear on the earth and that man has reached the limit of his possible physical and intellectual development. Social development is the only path left open for him, and just as evolution has progressed from the individual to the family, the tribe, and the modern State, so some day it will bring the whole human race together into a federation of the world.

The argument rests on many disputable statements; the intellectual, as distinct from the æsthetic, superiority of the Athenians over the moderns may well be questioned, as may the statement that the "great increase in nervous and mental disorders" indicates that "the evolution of the brain and nervous system of man has practically reached its limit." Hardly adequate credit seems to be given to Samuel Butler for his illuminating idea of "detachable limbs," nor to Benjamin Kidd for his "Social Evolution" and "Science of Power." The great goal towards which the human race is moving being the rational organisation of society, the author next turns to the question as to whether democracy will serve this purpose. This section of the book is chiefly of interest for its demonstration of how far the Americans are at present from appreciating what democracy is about. It is commonly thought, says Prof. Conklin, to involve the idea of maximal individual freedom and minimal social control; freedom is exalted above service, and "Liberty" is stamped on the coins with pictures of an Indian and a buffalo to show what it means. This, he points out, is a very primitive state of mind and recalls, from Huxley, that each bee has its duties and no bee has its rights; what is wanted is social coöperation rather than class antagonism, reason instead of passion, humanity in place of nationalism. Noteworthy is the expression of the conviction that the further progress of humanity will necessarily involve the breaking down of the segregation of white and coloured races. Man is a wild animal and there is no one to domesticate him; he combats and overcomes the cosmic processes that dominate other animals; pure lines and selected breeds are therefore impossible. Democracy, with all its faults and difficulties, is the only route for further evolution. There is in this section of the book so much that is opinion rather than fact that criticism in brief is hardly possible. But it is not clear that the author has realised that democracy is a means, a mode of freedom, not an end in itself. The final third of the book deals with evolution and religion, and here the author becomes obscure and difficult to follow beyond his obvious thesis that there is nothing incompatible between natural knowledge, evolution, and religion. Prof. Conklin is a rationalist and he finds the usual difficulties in applying his intelligence to an analysis of his relation to God. Sundar Singh remarks that milk does you more good if you drink it than if you analyse it, and advises you to take religion in the same way; Bosanquet says much the same. But Prof. Conklin's gospel is that you get more real benefit from analysis, and he proceeds to consider how that is to be done in a series of chapters which are interesting but not very illuminating.

The book as a whole can be warmly recommended to those who are curious about the relation of mankind to the world; it is suggestive and provocative, an effect enhanced by the jerky style and ejaculatory method of presentation; it would do splendidly for reading aloud in a small circle for discussion. Some possibilities are not discussed and it would be interesting to hear the author's views on the likelihood that the route for further human progress, which he can see only in social coöperation, is along lines which, in our present terminology, we should call spiritual; the path at any rate is probably not an altogether obvious and intelligible one, else we should be on it already. Laying, as he does, so much stress on the lessons about the course of evolution which we can collect from its past history, it is surprising that he does not deal more fully with the chance that mankind is "destined" to suffer the fate that is known to have overtaken so many large and highly-specialised vertebrates and be completely obliterated. Perhaps his cheery and stimulating optimism deflected him into more encouraging topics.

CEREBRO-SPINAL FLUID.

Liquido céfalo-raquidiano. Its Clinical Value Estimated from Observations in the Laboratory of Prof. Alberto de Aguiar. By Prof. ALFREDO DA ROCHA PEREIRA, of the Faculty of Medicine of Oporto. Oporto: Companhia Portuguesa Editora. 1921. Pp. 336.

THIS work is divided into five parts and a bibliography. The first part, describing the normal cerebro-spinal fluid, its anatomical and physiological characters, and its composition, calls for no particular comment. In the second part the variations from the normal are dealt with, the aspect and colour, tension, the presence of albumin. Froin's syndrome (massive coagulation and xanthochromia), albumino-cytological dissociation, Noguchi's reaction, and the presence of urea, chlorides, and glucose. Chapters are also last year, bearing on the pathological physiology of Jacksonian epilepsy following gunshot wounds of the head. Mr. LERICHE took the occasion to examine his patients in the seated and not the recumbent position, the tension of the cerebro-spinal fluid being very different, according to him, when the subject is seated, and when a local and not a general anæsthetic is employed. In these circumstances he has observed on several occasions that the onset of a Jacksonian fit is immediately preceded by an arrest of cerebral pulsation and by instantaneous blanching of the cerebral pial vessels at the same moment; and he has made the further observation, in similar experimental circumstances, that in a large number of Jacksonian cases the tension is below rather than above the normal. Such observations, coupled with those made by Mr. SARGENT, seem to warrant closer investigation with wider material, for their bearing on the pathogenesis of epilepsy is at once apparent. Mr. SARGENT is led, from a consideration of his great, if not indeed unique, experience of gunshot head wounds in connexion with epileptiform attacks, to suggest that one of the most frequent causes of local circulatory disturbance, and so, ex hypothesi, of convulsions, depends on the fixation of the brain at the point of damage to the overlying membranes and scalp; it is occasioned by the cerebral movements. It is true, no doubt, that but a small proportion of patients with "anchored brains" develop epilepsy, and the fact suggests the question of a possible constitutional factor and of neuropathic inheritance. Mr. SARGENT sees in a "low degree of stability of the nervous tissue" that undefined something from the necessity of postulating which the student of epilepsy cannot apparently escape. Here we find ourselves in the region of the imponderabilia once more, and it is precisely here that the door is left open for the intrusion of speculation if not of fantasy.

We shall welcome the result promised of Mr. SARGENT's operations on some 120 patients suffering from epilepsy following on gunshot wounds of the head, and the communication will, we feel sure, be enhanced in value by the inclusion of information as to the individual constitutional inheritance of the patients operated on. If only some 5 per cent. of patients with head injury sustained in warfare develop subsequent epilepsy, and if they do not all show some definite traumatic cranial defect, then clearly trauma alone is inadequate to cause convulsions, and the necessity of authoritative investigation of individual antecedents is more than ever patent. As for the group of idiopathic epilepsies, Mr. SARGENT declares that at the present time surgery has nothing to offer by way of treatment; in any case he deprecates recourse to surgical interference if medicinal and other therapeutic measures cannot be prosecuted at the same time over a long period.

◆

Epidemic Situation in Soviet Russia.

THE new Health Committee of the League of Nations, which met in Paris on Oct. 20th to 23rd, received an important communication on the present epidemic situation in Russia from Dr. NORMAN WHITE and Dr. L. RAJCHMAN, who have just returned from a visit to Moscow in their capacity as members of the Epidemic Commission of the League of Nations. It had been decided that the work which this Commission has accomplished in dealing with the risks of spread of epidemic diseases from Russia to the States which border that country on the west should as far as practicable be supplemented by inquiries in Soviet Russia itself, and the Commissioners have already succeeded in obtaining much valuable information as the result of their visit, a report of which is promised at an early date.

In view of the persistent reports of outbreaks of plague during recent years it is interesting to learn that in European Russia not a single case of plague has been officially verified. Cases have been reported but immediate bacteriological inquiry has in each case negatived the diagnosis. There was, however, a real outbreak in Batum, where prompt recourse was had to anti-plague vaccination on a considerable scale. The outbreak of cholera which has been so severe in the regions of Russia affected by scarcity and famine in the summer months of the present year is reported now to have come to an end very abruptly and unexpectedly; no adequate explanation is, however, so far forthcoming for this rapid cessation. As regards typhus, official notifications aggregate more than two million cases in 1919 and nearly three million in 1920. It is acknowledged by the Russian authorities that these figures very much understate the gravity of the outbreaks. It is estimated that if the Caucasus, Siberia, the Ukraine, and other parts of Russia for which no figures are available, be included, the number of typhus cases in these two years would approximate to 20 millions. Epidemic typhus has been less severe during the present year, but it is difficult to forecast the severity of the outbreak to be expected in the coming winter season, and it is noteworthy that this disease is already again prevalent in the areas afflicted by scarcity and famine. During 1921 relapsing fever has been more prevalent even than typhus; a similar state of affairs has been reported from contiguous parts of Poland. It has caused much sickness, but, as usual with this disease, very little mortality. At the present time enteric fever is very widespread and is causing considerable anxiety to the Russian public health authorities. Dysentery has not been very serious, though a very severe outbreak was experienced in Petrograd in 1920, when the mortality rates were very high. Small-pox is widespread but is not considered to present a very serious problem; vaccination has been very extensively carried out in the affected areas. Malaria has been extremely severe in the Volga districts; while a considerable outbreak of malaria was reported this summer as far north as Archangel.

Venereal Clinics and their Clients.

AT a conference of the Western District Branches of the National Council for Combating Venereal Diseases, held recently at Bristol, one of the main topics of discussion was the difficulty of securing the attendance of patients at treatment centres until they have been rendered non-infective. Medical officers of health, not for the first time, raised this question and insisted on its importance. A summary of the reports of the London County Council on venereal diseases, for which Dr. F. N. K. MENZIES and Colonel L. W. HARRISON were responsible, has dealt with the matter,[1] as did proposals made by a subcommittee of the Liverpool City Council, which were included in the annual report for 1920 on the health of Liverpool by Dr. E. W. HOPE. There is, in fact, a consensus of informed opinion as to the existence of the loss of efficiency involved by this discontinuance of treatment, and as to the desirability of dealing with it. But although the situation is beyond dispute it may be difficult to secure unanimity between Parliament, the medical profession, and the public as to the best course to be discussed and a list of tests is given for the presence of impurities other than alcohol, which the pharmacopœias usually insist on. A lengthy and interesting article on alkaloids is written by Mr. B. F. Howard and Mr. O. Chick. The history and cultivation of cinchona, and the many alkaloids found in the barks are described. The quinine market is a curious one and, considering the extent to which this drug is used in the British Empire, it seems remarkable that we cannot make all the quinine we require by undertaking the scientific cultivation of cinchona in our colonies, instead of being subject to the control of Dutch merchants. Contributions on camphor, cocoa, coffee, cheese, and particularly on disinfectants, will repay perusal. Throughout the volume few errors are noticeable; the writing is clear and the editing admirable.

AUTOBIOGRAPHY OF AN ANDROGYNE.

New York: The Medico-Legal Journal. 1918. Pp. 265. $4.

THIS is the auto-biographical story of a life-long struggle between devoutly religious ideas and intensely perverse desires. The book is not for general reading, but whoever is called upon to deal with disorders of impulse and conduct—whether he be doctor, lawyer, or legislator—will act with fuller justice if he has such knowledge as a book of this nature can give him.

A MANUAL OF PHARMACOLOGY.

Fifth edition. By WALTER E. DIXON, M.D., F.R.S., Reader in Pharmacology, Cambridge University. London: Edward Arnold and Co. 1921. Pp. 468.

THE new edition of Dr. Dixon's Manual of Pharmacology has nothing to fear from critics. The strength of the book is the common-sense way in which the author, who knows all there is to be known on the subject of pharmacology, limits what he imparts to the useful and applicable side of the drugs. He gives the information which counts. The non-therapeutic drugs receive their due without being over-emphasised. The book does not aim at any theory in arrangement and is essentially practical; thus many-sided drugs like the atropine group and sulphur do not break down any high-aiming scheme. Dr. Dixon has by his pharmacological work been in part responsible for the recent revival of the application of physiology to medicine, which implies also a revival of pharmacology. This book is the summary of his own and others' work which has made this revival possible. It is a manual of pharmacology which does not encroach on therapeutics. If students could be persuaded to learn scientifically, considering the actions of drugs in the manner laid down in the early pages of the book, learning would be easy; instances given there make the rest of the book simple reading. The tracings and formulæ, which at first sight suggest that the book may be technical and tedious, are found on nearer examination to add materially to the interest of the text. We note that Dr. Dixon assents to, but is not an enthusiastic adherent of, the myoneural junction theory, and that he considers that alkalies taken before food do inhibit the secretion of gastric juice; recent work would hardly seem to support this view. As regards minor details of accuracy the book is excellent.

The fifth edition is well up-to-date and is not hampered by old formulæ and out-of-date drugs. It is, we believe, the best book of its class on pharmacology.

JOURNALS.

HEALTH: JOURNAL OF THE FEDERATION OF MEDICAL AND ALLIED SOCIETIES, 12, Stratford-place, London, W. 3*d*.—The journal of the Federation of Medical and Allied Societies has made its appearance this week, and states concisely on the title page its object. It is "concerned in assisting the formation of opinion on public health questions." In a lucid foreword by Sir Malcolm Morris this idea is further explained: "It is not enough," writes Sir Malcolm Morris, "that the leaders of the societies should meet in conference as they are doing. If this great combination is to pull its full weight, it must be sustained by an instructed and vigorous public opinion in the membership. The rank and file, numbering scores of thousands, must be brought into the debate. They must be kept informed of what is afoot, they must have opportunities of adding their knowledge and wisdom to the common stock. That is why *Health* has been started." The contents of the new journal, modest though it is in size and price, fairly live up to a large promise. A statement of the position under which an inquiry into the working of the Insurance Act is being sought for is followed by an excellent special article on the voluntary hospitals and the national provident scheme, by Dr. Gordon Dill. The *revue* of the week takes particular notice of the public interests in such questions as grants towards milk for necessitous mothers, the payment for insurance under the Unemployment Insurance Act by nurses, and the exemption of nurses and midwives from juries, now that women can take their place in the box. A thoughtful article by Dr. Jane Walker upon the question of whether marriage should be regarded as a bar to the employment of women deals with a matter of topical urgency. The diary of the proceedings at the meetings of societies and associations where these and similar subjects are discussed forms a useful section of the paper, and one which is probably intended to become a regular feature. We wish our contemporary all prosperity.

ANNALES DE L'INSTITUT PASTEUR.—In Vol. XXXV., No. 8 (August, 1921), Gengou has taken up the study of the substances causing breaking up of bacteria within the leucocyte, and by extracting with acids and neutralising the product obtains a substance capable of producing a similar result in vitro. Since the morphological changes undergone by the bacteria under these circumstances are the same as those occurring within the leucocyte in vivo he considers that his extracts contain the active substance of the leucocytes. Other tissues fail to give similar extracts. The extracts are only active within a moderate range of alkalinity or acidity on either side of neutrality. The extracts contain a single substance capable of acting on a variety of organisms, not specific substances for different organisms. The active substance is protein in nature or closely bound up with the proteins of the extract. They exert no hæmolytic action on red blood corpuscles, and cannot be made to do so by the addition of either fragment of the complement from which, and from other considerations, Gengou considers this substance distinct from complement, and, although capable of digesting gelatin, also distinct from the proteolytic ferments of the leucocytes.—The Mechanism of Action of Hirudin and the Antithrombin of the Plasma obtained after an Injection of Peptone, is the subject of a long paper by André Gratia. The author accepts the classical theory of coagulation, as enunciated by Bordet and Delange, which assumes the presence of three substances essential for coagulation: a thermolabile humoral substance (serozyme), a thermo-stable cellular product (cytozyme), and fibrinogen. He accepts the lipoidal nature of the cytozyme and habitually uses a lipoidal extract as cytozyme in his experiments. In general the antithrombin of peptone-plasma and that of hirudin have similar properties; he does not agree with Mellanby and others that the former, like that set free in anaphylactic shock, is merely an increased alkalinity of the blood, but considers it a specific substance. Both these antithrombic substances have the property of being effective in much smaller doses the earlier they are made to intervene in the process of clotting; a quantity capable of inhibiting the combination of serozyme and cytozyme to form thrombin being insufficient, at a later stage, to neutralise the thrombin when once this is formed. The amount of hirudin required

Annotations.

"Ne quid nimis."

FRENCH GOVERNMENT AND TOWN SANITATION.

PARTLY to facilitate the increase of population, which is so necessary in France, and partly in the hope of finding work for the unemployed, Mr. Leredu, the Minister of Public Health, has addressed a circular to all the Prefects, in which he points out that the laws on public health sanction special investigations as to the sanitary conditions of towns. The Minister is urging that a thorough inquiry should be held in all towns where the death-rate is above the average. The use of such a measure is obvious, particularly as during the war little or nothing could be done in respect to domestic or public sanitation. If the waterworks, the sewers, the disinfecting stations, were kept in good working order, it was the most that could be expected under the circumstances. But much more was needed, and is now in some places very urgently needed. It may be asked, however, if the fact that the death-rate is above the average is a sufficient reason for neglecting other places where the death-rate is below the average. A town may have a very low death-rate, taken as a whole, and yet there may be a scandalously high death-rate in one or two special districts. Indeed, it is just because the general conditions are so good that the exceptionally dark spots are apt to be overlooked. These slums, bad in themselves, are likely, in times of epidemic, to be centres from which the whole town is infected. During the last great cholera epidemics this was the case, especially at Havre and Hamburg. At Hamburg the deaths from cholera varied from 4·48 per 1000 inhabitants in the Harvestehude district to 27·50 in the Vedde district. Yet all had the same water-supply. At Havre, some of the localities most afflicted had an ordinary death-rate, before the epidemic, of 50 per 1000 per annum, though the town, as a whole, was not particularly unhealthy. Such contrasts are to be found in many large towns, and a moderate death-rate cannot be taken as evidence that plague spots do not exist. Sanitary commissioners have visited and described for us in these columns many such unwholesome streets, blocks of houses or districts which exist in London and in various provincial towns, in England as well as in large continental cities. In Paris, to this day, close to the seat of Municipal Government, the Hotel de Ville itself, and further off, in the XVIII., XIX., and XX. arrondissements, there are still numerous streets where the death-rate is very high and where drastic measures are urgently needed. In such circumstances, all local authorities, whether the general death-rate is high or low, should be called upon to deal with their slums, thus finding, moreover, work for the unemployed while benefiting public health.

CURE DE JEÛNE IN DIABETICS.

IN a recent article[1] Dr. Marcel Labbé describes his experiences with the method of treating diabetes mellitus by means of starvation. He gives the credit to his French colleague, Dr. Guelpa, who introduced a form of fasting and purgation treatment in 1910, but at that time he was not much impressed. The work of Allen and Joslin caused him to experiment again with the fasting treatment with the result that he modified his views. He found that the treatment was of great value in treating diabetic patients who had not lost weight. The glycosuria disappeared and the ketosis was much reduced. He was convinced, however, that the treatment was not a cure, using the word in the sense of a complete restitution. Allen, it should be pointed out, has never claimed that it was. Labbé does not believe that the treatment is of use for the patients who have lost weight, giving several instances in which the glycosuria either did not disappear or reappeared again as soon as any attempt was made to feed the patient. These patients also tended to pass into coma very suddenly. It is, of course, well recognised by those who use the fasting treatment in this country that patients with severe and advanced diabetes have already passed beyond the stage in which striking improvement can be expected. Nevertheless, fasting may improve the condition of the patient enormously since it removes the thirst and pruritus which render his life a misery. For the sake of the diabetic patients in France it is to be hoped that Dr. Labbé's article will induce his colleagues to read the numerous papers and books published in America and also in England, and to practise, with discrimination, the fasting treatment, which was so fully discussed before the Medical Society of London last week (see p. 957).

A RED CROSS HEALTH CAMPAIGN.

IN a paper recently published Dr. C. E. A. Winslow,[1] Director of the Department of Health, League of Red Cross Societies, sketches a programme for a Red Cross health campaign which commands sympathy from the breadth of outlook shown. Nothing less than the amelioration of "all woes of all men"—to quote Swinburne—is contemplated as worthy of the Red Cross, the deepening and broadening of whose ideals is counted by Dr. Winslow as among the greatest of the compensating gains of the war. Of the magnitude of the task thus visualised there can be no question. An annual loss of 9½ million lives in Europe alone from so-called "natural causes" represents a staggering volume of illness and suffering, largely preventable; and it is to the preventive character of the peace-time efforts of the Red Cross that Dr. Winslow draws special attention. The journal in which he writes is itself one of the most interesting and useful developments of international Red Cross activity.

To ensure the voluntary coöperation of the individual citizen without which Government and municipal health authorities can effect little, an educational campaign is imperatively demanded, although the wide diversity of conditions in the different countries makes adherence to any rigid plan undesirable—and, indeed, impossible. Dr. Winslow suggests as a basic feature in a health programme the local establishment of a system of classes under the leadership of the Red Cross, for the study of the principles of hygiene and of local health conditions and needs; a scheme of lectures suitable for this purpose should be outlined, and the practical details connected with the organisation of an adequate health education programme set out. In localities where special societies devoted to particular phases of public health work already exist, the Red Cross may play an important part in coördinating their work and facilitating its execution, an example of this being the agreement entered into in this country between the British Red Cross and the national societies devoted to child welfare, tuberculosis, and venereal disease. Dr. Winslow's scheme is, however, in its essence elastic, and while in many countries child welfare work or tuberculosis work is already adequately covered, he is emphatically of the opinion that in almost all countries there is some important gap which the Red Cross can fill. A section of the paper is devoted to a consideration of the objections that have been or might conceivably be raised to the initiation of such a health programme by the Red Cross. These objections are stated with fairness, but are fully met, and a strong case made out for the extension of the Red Cross functions to a definitely constructive policy—not indeed in any way competing with established organisations or institutions, but

THE LANCET.

LONDON: SATURDAY, NOVEMBER 5, 1921.

Of Clinical Units.

THE clinical units, which have been established for some two years at several of the London and provincial general hospitals, mark a new era in the attempt to solve the problems of medical education, and at the same time they indicate an effort to promote the scientific study of medicine. It is too soon as yet to assess the progress made, but it is not too soon to attempt an estimate of their chances of success or failure. The formation of these units has evolved from the desire to explore old ground by new methods, as Sir CHARTERS SYMONDS recently said of the Hunterian era, and their establishment marks the close of a system of professional education which, until quite recently, had been a private enterprise. In no other country than our own could a complete system of medical education have been maintained continuously by private effort, and there are some, no doubt, who will deplore the modification of a system that has attained so large a measure of success. Reform is welcomed in the face of failure, but in the face of great results it requires close justification. Though the time is not ripe to pass judgment on the unit system, its existence is beginning to awaken general interest and its sphere of activity to take a more concrete form; as recent communications to THE LANCET have shown, informed opinion is crystallising as to the more immediate aims that the clinical units should keep in view. Elsewhere in this issue there appears an article by Sir CLIFFORD ALLBUTT, which, though it claims only to be a comment on an article on clinical units by Dr. C. M. WILSON, of St Mary's Hospital, is in itself an inspiration to all who have the interest of medical education at heart.

If the new clinics could attract visitors from foreign cities to British medical schools they would at once be missions with a more than medical significance. In pre-war days the German and Austrian medical schools were centres for the dissemination of continental thought, and with every year that passes we can, as a nation and as a profession, less afford the island isolation that was once our boast. In the more immediate field of work Sir CLIFFORD ALLBUTT counters an implied objection to the unit system, an objection based on the assumption that the teaching of professors of medicine—that is, of men who do not practise medicine in the ordinary sense—will be theoretical rather than practical, and that these attitudes of mind must be poles apart. When science was in its infancy its votaries were often abstract thinkers, but with the development of controlled experiment a new type of scientist has been born. He is a man with vision and imagination, who pursues his goal undeterred by side-issues and undismayed by failure; at the same time he is a man of fact and practical ability, using dispassionate observation and experiment as his working tools. Such men are a composite in themselves of what is practical and theoretical. Convincing proof of this was furnished in the war when the nation applied to the purest scientists for practical help and physicists and chemists turned their energy to the manufacture of engines of destruction, and biochemists laid down the principles that determined the rationing of our armies in the field and the civilian population at home. In the matter of teaching Sir CLIFFORD ALLBUTT looks to the units to take their share in the pioneer work of advanced teaching, but if they follow the lead of the great universities, in which their members have been trained, their directors will take a share in undergraduate teaching. It is well known that principles are more difficult to inculcate than details, and that advanced teaching is a simple matter for anyone who has made an intensive study of the subject he is called upon to teach. In our older universities it is the practice for the elementary courses of instruction to be given by the professors, while the more advanced lectures are given by lecturers and assistants, and by the professor himself only in that particular subject in which he has a special knowledge.

Those who are responsible for medical education, and especially those who are interested in the success of the clinical units, will guide the workers in these units in balancing the somewhat conflicting demands which are made on them by the duty owed to the patients under their care, which must necessarily come first; by teaching, whether graduate or undergraduate; and by research, without which any teaching must lose its inspiration. With the small staffs of which these units are at present composed these demands may become insistent and deprive the workers of the leisure required for the assimilation of new knowledge and for research. Though the personnel of the units may be spared the care and strain of private practice, the units in bulk must be on their guard against the temptation of striving to arrive at maturity too soon. They have a difficult path to tread before they can achieve full success. The enthusiasm and vigour that is part of a new life or a new idea will not be lacking, but diligent consistency in following defined aims will best attain the end in view.

◆

Observations on Epilepsy.

THE presidential address delivered by Mr. PERCY SARGENT before the Section of Neurology of the Royal Society of Medicine bears on certain as yet unsolved problems connected with epilepsy, and is the more welcome in that it is written from the viewpoint of the neurological surgeon. Sharing, apparently, the recently expressed opinion of Dr. JAMES TAYLOR that the attempt to enmesh epilepsy in the net of psycho-analysis represents a definitely retrograde movement, Mr. SARGENT devotes himself to a discussion of the pathogenesis of convulsive seizures, and in this connexion admits that he has been impressed by the striking rapidity with which visible circulatory changes occur in the exposed cerebral cortex in response to various disturbing causes. The vascular theory, as it may be called, of spasmogenesis was sustained and illustrated by Dr. A. E. RUSSELL in his Goulstonian lectures of 1909, and it is examined afresh by Mr. SARGENT with the aid of personal observations. His suggestion is that the tonic stage of an epileptic attack is the sequel to sudden and transient disorder of the cortical circulation, resulting immediately in a "decerebration" such as has been recently the subject of clinical study in man, while clonic movements may conceivably be the expression of returning circulation. Mr. SARGENT cites a personal experience from the laboratory of Prof. C. S. SHERRINGTON, when the pia mater was seen to blanch during the application to the cortex of a faradic stimulus of sufficient strength to evoke epileptiform movements. This observation is not, of course, new, and yet the phenomenon may not have received the attention it merits.

An interesting article[1] was published by Mr. LERICHE consider it desirable that a standard of accuracy should be set up which will show the British article to be above suspicion; they recall the fact that the Order in Council for the compulsory testing of clinical thermometers, which operated from November, 1918, till March, 1921, resulted from the discovery that many instruments supplied to the army were found too inaccurate for use. Large contracts had been hastily placed with every maker, and production was increased regardless of quality. The first tests revealed serious inaccuracy in 25 per cent. of instruments tested; rejection of this proportion speedily reduced the percentage to 5, and at the time of the abolition of the test the rejections had fallen to 1½ per cent. In November, 1919, 135,000 thermometers were tested monthly, under the compulsory regulation: in March, 1921, when the testing of exported thermometers was abolished, 65,000 were submitted, and in June, when the compulsory test was itself abolished, 55,000 was the quantity under test. We agree with the manufacturers who are responsible for the publication of this circular that it is superfluous to comment on the unwisdom of abandoning the principle of a strict test at a time when France, Japan, Germany, and certain States in the U.S.A. have all instituted compulsory legislation dealing with the matter. It will be recalled that a special clause, forbidding the sale of any clinical thermometer not approved by the Ministry, formed part of the Ministry of Health Miscellaneous Provisions Bill introduced in 1920. On the occasion of the defeat of that measure in the House of Lords one speaker referred to the clause in question as an example of grandmotherly interference; but in the report for 1919 of the National Physical Laboratory it is stated that in one month of that year, of 9000 clinical thermometers submitted for testing by a single firm, 28 per cent. were rejected as being in some way unfit for use. The medical man can no doubt see to it that his own instruments are accurate, but when the periodical taking of temperatures is left in the hands of a lay person the use of a faulty thermometer may be attended with disastrous consequences.

PHYSICAL EXERCISE IN HEART DISEASE.

DR. C. W. Chapman called attention in our correspondence columns of Oct. 22nd to the merit of the Burke Foundation, N.Y., in popularising the notion of occupation therapy for cardiac patients in America. Not long ago Sir James Mackenzie[1] described the observation of response to effort as the most important method of estimating the heart's efficiency, adding that the method is "apparently so simple that everybody feels confident that he has recognised it, used it, and exhausted its possibilities," while, as a matter of fact, few people have given it the study it requires. It is no less true that physical exercise as a therapeutic measure in cardiac disease has suffered from neglect, a lacuna which Dr. Theodore Barringer, jun.,[2] in a recent paper on the subject, ascribes mainly to the prevalent but mistaken idea that the chief cause of heart failure in patients suffering from cardiac disease is physical overstrain. In an earlier investigation made by him[3] of the clinical records of 154 cases of heart failure complicating chronic valvular or myocardial disease, it was found that in only three cases was there a definite history of physical strain immediately preceding the onset of symptoms, the dominant factor undoubtedly being that of infection. Dr. Barringer in his later papers describes the blood-pressure reaction during and after exercise in normal persons and in persons with heart disease. In the normal individuals experimented on it was found that the pressure rose during work, the degree of rise being proportional to the intensity of the work; and that this height was maintained for the first 60 seconds after work. In the patients with heart disease the pressure which rose during work rose still further on the completion of the work, the rise at both periods being much more marked than in the normal controls. A delayed rise and prolonged fall were noticed whenever the work over-taxed the heart. As the object to be aimed at in giving exercise to a diseased heart is so to grade the exercise that the heart muscle is stimulated to contract more energetically, thus increasing both the output per beat and the supply of blood to the muscle while avoiding any degree or duration of exercise which would fatigue the heart, the height of the blood-pressure curve affords in the majority of patients a convenient indication as to the effect of a given exercise on the heart. A rise of more than 20 mm. of mercury from the pre-exercise level indicates an energetic and favourable reaction in the absence of any signs of over-taxation of the heart. Among the forms of exercise recommended by Dr. Barringer are various movements with dumb-bells from 1 to 15 lb. in weight, stair-climbing, and skipping, for the more energetic exercises, and walking, croquet, and arm and leg exercises for the milder forms, the selection of the particular type for each case being based on the amount of increase in the systolic blood pressure after exercise. The mild form should as a rule be used for patients with small cardiac reserve power, and also to supplement the more energetic exercises. Dr. Barringer concludes by a statement of his opinion that physical exercise increases both the resistance to general infections in patients with heart disease precisely as it does in normal people, and the resistance of the heart muscle itself to reinfection leading to heart failure, insisting that there is no excuse in most cases for advising heart patients against exercise, or for vagueness and indefiniteness in prescribing this valuable therapeutic measure. Dr. Barringer's findings refer mainly to adult patients, but Dr. May Wilson[4] studied the circulatory reactions to graduated exercises found in normal children and obtained similar results. She also formulated a working table of standardised test exercises followed by normal systolic blood-pressure curves without symptoms of dyspnœa and fatigue, by the use of which she convinced herself that in children with chronic organic heart disease exercise tolerance tests are of undoubted value as a scientific basis for the regulation of the child's activities. Dr. Wilson endorses Dr. Barringer's dictum that the widespread fear of exercise in heart disease is unwarranted.

COORDINATED HEALTH SERVICES IN WILLESDEN.

AN interesting feature of Dr. G. F. Buchan's report for 1920 as medical officer of Health for Willesden urban district is his description of a scheme for the coördination of medical services. This scheme Dr. Buchan claims to be much on the lines indicated in the Dawson Report and to have been set going two years before this report appeared. For purposes of health organisation Willesden is divided into four areas of approximately equal size, each of which is in charge of an assistant medical officer, who is the pivot of the public medical work of his area and controls within his district infectious diseases, maternity and child welfare work, and school medical work. He has at hand for the elucidation of cases of difficulty, the services of part-time consultants appointed by the urban district council and a hospital with beds for the observation or treatment of cases when necessary. In this way Dr. Buchan is satisfied that there is available for patients attending the council's clinics the best possible medical skill for diagnosis and treatment. He admits that neither the clinics nor the hospital are as yet fully equipped, but when this is achieved the mothers and children will be in a position to know that the local authority has left nothing to chance in its endeavour to secure healthy child life. The advantage of the medical arrangements consists adopted. The treatment of venereal disease at clinics has been instituted that the sufferings of individuals infected may be alleviated without expense to themselves, and also that so far as persons presenting themselves for treatment are concerned, the infection of others by them may be averted and the transmission of venereal disease by infected persons, including parents, checked. The cure of the patient is not the main end aimed at but one of the means by which a measure of prevention may be attained. Universal treatment of all persons suffering from venereal diseases is out of the question, at present at all events, but two objects have to be kept in view in striving towards that ideal. These are the attracting for treatment of as many patients as possible and the effective arrest of the disease so far as they are concerned. The former is largely a matter of rendering all the circumstances of treatment at a clinic as little repellent to infected persons as possible, and of inducing them to seek it by diffusing the knowledge that everything possible will be done to relieve them, provided that they will do their share conscientiously. According to estimates made by those qualified to judge, the persons who do not persevere until there is no fear of their infecting others constitute not less than 30 per cent. of the number treated, and may in some localities amount to 60 per cent., so that to this large extent the clinics fail in fulfilling their mission. Dr. R. E. Roberts gave one such estimate in our own columns (August 6th, p. 277).

[1] THE LANCET, June 11th, 1921.

[2] Jour. of Amer. Med. Assoc., July 2nd, 1921. Amer. Jour. of Med. Sciences, July, 1921.

[3] Jour. of Amer. Med. Assoc., April 23rd, 1921.

[4] Amer. Jour. of Diseases of Children, September, 1920. Jour. of Amer. Med. Assoc., June 11th, 1921.

As causes of this defect, lack of better conditions for treatment, and failure to attract patients no doubt play their part. There remain also to be taken into account the careless recklessness of the uneducated patient, the optimism which mistakes the relief of the more distressing symptoms for a completed cure; the difficulty of explaining absence from work or from home in attending the clinic; and the call of various occupations, such as those of the seaman or commercial traveller—the list is not exhaustive. The London County Council report deals in detail with the conditions desirable in clinics, and with the other causes of interrupted treatment. At the meeting at Bristol it was suggested that some form of administrative procedure might be instituted which would induce, if it did not compel, attendance to the point at which no further danger of the infection of others is possible. Legislation to compel persons suffering from venereal diseases to seek early and adequate medical attention seems to us to be out of the question—those who talk glibly of such measures are not living in a world of facts. There is, however, plenty of evidence that the offering of free treatment to those who may seek it voluntarily is so far appreciated that many clinics suffer rather from congestion and from the difficulty of dealing with the flow of patients than from the lack of them. The L.C.C. report plainly suggests that overcrowding, long periods of waiting, and inadequate opportunity for attention during examination contribute to promote the lapses in perseverance. There is, therefore, a considerable number of persons to be treated, although all may not offer themselves, while legislation to compel the public to do more than they do already appears not to be practicable. Anyhow, the time is not ripe for such procedure, but it may be possible to effect considerable improvement without it. The example of other countries affords us some guide. Without the exercise of such compulsion there remains the power of persuasion, instruction, and advice, exercisable already where there is time and the necessary personnel to apply it. There is, further, the practicable course, if it were to be introduced, of following up cases from the clinic to the home, whenever the patient, still capable of spreading infection, appears to have discontinued treatment. The officer from the central office, or the clinic, the almoner or the health visitor would seek out the man or woman, and endeavour by persuasion and personal influence to bring him or her back to the clinic. The objection would, no doubt, be made to such a proposal, that the promised and advertised secrecy of the clinic's treatment would in such cases be liable to be sacrificed, and the efficacy of the whole scheme impaired by a deterring influence thus aroused. It is, however, open to question, as some who have had practical experience maintain, whether the persons seeking treatment for venereal diseases at clinics, or at any rate the men so situated, attach quite so much importance to the concealment of their condition as many believe. Men and women of mature age and of a different social standing from the young people affected may overrate the value of secrecy.

But even if the dread of disclosure exists to the full extent imagined, it might conceivably be made to play a useful part in inducing perseverance in attendance at the clinic. If the patient were warned at the outset that the treatment sought would be given only on the condition that he must persevere to the end, he then, in the full consciousness of his symptoms and his need, would be likely to accept any terms so imposed upon him. He would, moreover, know after a time from the experience of his fellows what had happened in their case and would hesitate before discontinuing his attendance prematurely. He would learn that he could not throw up all the advantages which he had gained without an effort being made to reclaim him. It need hardly be said that the task of following up patients would have to be entrusted to persons of the appropriate sex carefully selected for the purpose, and to be carried out with tact and discretion. Consideration would have to be accorded to the case of women as distinct from men and also to the classes of women affected. It must also be admitted that the net could hardly be drawn in such a manner that none would escape it. The giving of false addresses and names by those seeking treatment no doubt takes place to an appreciable extent, and the giving of true names and addresses would, in any circumstances, remain difficult to enforce, at any rate in large cities and urban communities. Nevertheless, however great the difficulties may be and however imperfect the result likely to be obtained, the fact remains that the treatment now given is to an appreciable extent ineffective as a measure for the protection of the health of the community. Until public opinion is ripe for compulsory legislation it can be rendered more effective by eliminating from the clinic circumstances and conditions likely to deter patients from continued attendance; by impressing upon them at the clinic the vital importance for themselves and for others of persistency, even when to them the desired end appears to have been attained; and by such following up of cases as may be found in the light of experience to be productive of results. As in every other function of public importance already overtasking those who perform it, extended usefulness will demand in many cases increase of staff and will involve greater expenditure. The stage, however, has not been reached at which the financial difficulty or the precise extent to which voluntary effort may be utilised need be dealt with in concrete terms. Free discussion of the problems involved and the securing of appreciation of them by the lay public appear in the first instance to be desirable. They would form a necessary preliminary to any tentative measures that might follow.

and from the changes which sometimes take place late in life as the result of an alteration in the refractive index of the crystalline lens, these changes have attracted little attention; many an oculist when he finds a difference of, say, half a dioptre of astigmatism in the refraction of a patient compared to the record of his earlier adult years is inclined to attribute the circumstance to an error of observation on the former occasion, whether on his own part or on that of a colleague. It is satisfactory to be assured by one who has recorded these changes during a period of 40 years that they do actually occur. Mr. Clarke did not explain the mechanism by which they are effected. In the case of an increase in the axis of the eye in one meridian we can understand it by supposing a yielding of the sclera, as in myopia. In the case, however, of a decrease of myopia or increase of hypermetropia or hypermetropic astigmatism, it is difficult to understand, unless we suppose that at the first test the ciliary muscle was incompletely paralysed. A still more difficult phenomenon to understand is an alteration in the axis of astigmatism which is said sometimes to take place. Since most tests for the angle of oblique astigmatism are subjective, the chances of an error of observation are considerable. Yet Mr. Harrison Butler, in the discussion that followed Mr. Clarke's paper, asserted that changes in the axis do actually take place—by what mechanism he did not explain. He did, however, remark that the angle of the cylinder required for reading glasses is sometimes different from that required for distance, and we may make the suggestion that the action of the oblique muscles, one of whose functions is to keep the axes of the eyes parallel, has something to do with it. The subject is one that requires further investigation on the part of those who have the opportunity of following up their refraction cases during a long series of years.

THE FIRST MITCHELL LECTURE.

THE history of the foundation of this lecture is as follows. The late Mr. F. W. Mitchell, a Birmingham manufacturer and a good citizen, was a liberal giver to any object which appealed specially to his views. He was interested in social-hygienic questions and had often expressed a wish to do something towards the "prevention and cure of consumption." With such an object in view he, altogether unsolicited, sent Sir Edward Malins a sum of money, which the latter forwarded to the Royal College of Physicians of London, and this was by the College used to found a biennial lecture on tuberculosis. To Dr. Parkes Weber has fallen the honour of delivering the first of these lectures, which will be found in the opening pages of this issue.

SUBLUXATION OF THE SHOULDER DOWNWARDS.

Dr. F. J. Cotton[1] has recently described a condition which appears to be not uncommon and yet has not previously received attention—subluxation of the shoulder downwards in cases of injury, due to the weight of the arm, and made possible by gradual exhaustion of the muscles, particularly of the deltoid. He has for years watched this condition occurring in case after case as a complication of shoulder and arm injuries, yielding promptly if treated early, becoming troublesome if neglected. He considers that many cases diagnosed as circumflex paralysis belong to this group. Dr. J. W. Courtney has shown that altered electrical reactions, even the reaction of degeneration, do not prove the nerve origin of paralysis or exclude a mechanical origin by stretching of muscle with consequent displacement of the head of the bone downwards. The type of case in which this occurs is uncomplicated fracture of the humerus, in which the weight of the heavy and perhaps swollen arm suspended, as in the routine treatment, only by the wrist, tires out the supporting muscles. A subluxation downwards, which is well shown in a radiogram taken with the patient standing, gradually appears. In the supine position the subluxation disappears. Eight out of nine cases seen in private occurred in women whose ages ranged from about 40 to 70 years. This fact is explained by the combination in them of a heavy arm with weak muscles. The subluxation is easily overlooked, but if the surgeon is on the alert, it can readily be diagnosed by finding a groove below the acromion, which is often visible and always easily felt. If untreated, the arm becomes helpless and stiff, the condition being not unlike that of subdeltoid bursitis, particularly the form complicated by supraspinatus rupture. Treatment consists of early massage, and, as soon as the main lesion allows, exchange of traction for support of the whole arm. Unless the neglect has been too long prompt improvement is obtained. In a quite recent case a stout but vigorous woman, aged 38 years, broke her humerus on April 19th, 1921. The treatment necessarily involved traction, cautious massage being used from May 10th. Traction was abandoned on June 1st and under support, massage, and exercises she recovered with a solid arm and nearly normal function of the shoulder. Older and less vigorous people require much longer treatment, but Dr. Cotton has never seen a case properly recognised and treated that had permanent disability. These cases show for a considerable time not a trace of deltoid power and several show definite electrical changes. He never sees deltoid paralysis from circumflex damage. All the cases seem to be either due to lesions of the brachial plexus or to the condition now described. Thus a photograph, recently sent to him of "isolated circumflex lesion" from a fall on the shoulder, showed marked atrophy of the scapular muscles as well as of the deltoid, and was obviously a partial traction lesion of the plexus.

AWARD OF THE JENNER MEDAL.

AT the first sessional meeting of the Epidemiological Section on Oct. 28th, the Jenner Memorial Medal of the Royal Society of Medicine was handed to Sir Shirley Murphy in recognition of distinguished work in epidemiological research. This medal was founded on the centenary of Edward Jenner's first successful inoculation of cow-pox from one human being to another, and has been awarded for pre-eminence in the prevention and control of epidemic disease. Dr. A. K. Chalmers, in bestowing the medal, spoke of Sir Shirley Murphy's name as worthy to follow those of W. H. Power, Laveran, and Patrick Manson. As the first medical officer of health for Greater London, he set himself quietly and firmly to clear up insanitary areas, whatever they might be, leaving the metropolis, as Dr. W. H. Hamer has put it, one of the best scavenged cities in the world. Sir Shirley Murphy's whole life has been spent in the endless task of caring for the health of London, and all over the world practical sanitarians will endorse the action of the Epidemiological Section in selecting him for signal honour.

THE resumption of the social evenings held by the Royal Society of Medicine was welcomed by a large number of Fellows and their friends who were received by the President, Sir John Bland-Sutton and Lady Bland-Sutton in the library of the Society's House on Oct. 31st. The success of the evening warrants the hope that such gatherings may now take place regularly.

LECTURES BY DR. MARMOREK.—Sixteen lectures, in English, on Experimental Medicine and Therapeutics, will be delivered in Paris by Dr. Alexander Marmorek at the Institut Océanographique, 195, Rue St.-Jacques, beginning Nov. 21st. The lectures will deal with such matters as: experimental production of specific human maladies, biological replacing of organs, experimental syphilis, tuberculin, origin of goitre and diabetes, proteinotherapy, and predisposition in infectious diseases.

---

[1] Boston Medical and Surgical Journal, Oct. 6th.

coöperating with and supporting all public health movements, and in certain cases possibly forming a central clearing house for voluntary activities of this kind.

The national Red Cross Society contemplated by Dr. Winslow is one that should include in its permanent membership from 10 to 20 per cent. of the population of the country, but he points out the impossibility of attaining such a standard unless the members receive something for their membership, and—an even more important point—are given something practical to do for the organisation of which they form a part. We agree with Dr. Winslow that the secret of the strength of the Red Cross movement undoubtedly lies in the fact that it constitutes a challenge to the spirit of human service.

TRYPANOCIDE.

IN a critical review[1] of recent work on the treatment of sleeping sickness, Prof. Warrington Yorke discusses the fundamental assumptions on which C. H. Marshall and S. Vassallo base their optimism as to the efficacy of serum treatment. These assumptions are, broadly speaking, (1) that although the administration of one dose of salvarsan or a substitute is sufficient to sterilise the blood-stream, symptoms reappear within a variable period, averaging about four months, and the disease progresses to a fatal termination; (2) that quite early in the disease the trypanosomes appear to gain an impregnable position in the central nervous system, where they are protected from the action of drugs and whence they can re-infect the blood. We recently pointed out[2] that the presence of trypanosomes in the cerebro-spinal fluid may be fortuitous, and it is by no means proven that they are invariably present at any stage in the course of the disease. Before the 53 successful cases published by Dr. Marshall are accepted as cures Prof. Yorke considers that we ought to know what proportion of cases (1) die, (2) are alive after more or less prolonged periods when untreated, when treated with one or several doses of arsenic or antimony compounds, and when subjected to prolonged treatment. In the absence of sufficient controls to answer these questions Prof. Yorke contends that Marshall and Vassallo have produced no satisfactory evidence that intrathecal injections of salvarsanised serum sterilise infected cerebro-spinal fluids. The doubt expressed by such an authority in tropical medicine as Prof. Yorke on the efficacy of the method which the mission recently organised by the Tropical Diseases Prevention Association was primarily designed to test, adds strength to our plea to the medical officers in charge thereof not to confine their investigations to a single method but to explore trypanocide in general.

CENTRAL COUNCIL FOR LONDON BLIND.

IN pursuance of the scheme for the welfare of blind persons in the County of London, which was approved by the London County Council in July last, the Council has now decided upon the constitution and order of reference to the Central Advisory Council which will be appointed under the scheme. The Council will consist of: (a) One representative appointed by each of 19 associations and institutions located in the London area. (b) Not more than six persons, selected by the London County Council, with special knowledge of the needs of the blind. (c) The chairman and vice-chairman of the Special Committee of the London County Council dealing with the welfare of the blind. (d) One representative appointed by the Minister of Health. (e) One representative appointed by the Board of Education. (f) One representative appointed by the Royal College of Surgeons of England. The County Council will review annually its appointments, and will appoint the chairman. The vice-chairman will be elected by the Advisory Council. The clerk to the London County Council will act as clerk. The order of reference to the Council will be as follows:—

> To assist the London County Council (1) by advising on matters specifically referred to it by that authority and on any other matters to which the Central Council may deem it expedient to direct attention; and (2) in such other ways as that authority may suggest in connexion with the administration of the scheme for the welfare of the blind in London, especially with the object of securing the essential coöperation between the several societies and associations and between such societies and associations and the London County Council.

All meetings of the Central Council and its committees will be held in private, and all expenditure incurred will, after prior sanction, be defrayed by the London County Council. The Special Committee is taking immediate steps to obtain nominations to the Council from the various associations concerned.

OVARIAN GRAFTS.

Prof. Th. Tuffier contributes a valuable surgical study of 230 ovarian grafts to a recent issue of the *Bulletin* of the French Academy of Medicine.[1] These operations were performed with the twofold object of preserving the menstrual flow after removal of the ovaries, when the uterus is left, and of obviating the general disturbance following excision of the ovaries and uterus. Two varieties of grafts were investigated, the homograft derived from another woman, and the autograft, which involved the use of a portion of the patient's ovary. The former was found to be without effect. The autograft, which must be fresh, was placed in the subperitoneal tissue, the subcutaneous tissue, or in the mammary gland. If the graft does not "take" it disappears in from six months to two years. In successful cases no changes were observed for four to five months, the graft then commenced to enlarge and might be painful for a few days before a period was due. When menstruation was re-established, it occurred about five to seven months after the operation, and was often irregular in quantity, duration, and time of recurrence. Dr. Tuffier found the most favourable subjects for grafts to be young adults; in patients over 40 years the grafts were not successful. The average persistence of menstruation in all cases was, however, only one to two years, as the transplanted ovaries appeared to undergo a precocious senescence.

THE TESTING OF CLINICAL THERMOMETERS.

IN reply to a recent question in the House of Commons concerning the inaccuracy of a large percentage of clinical thermometers in use in this country, Mr. Stanley Baldwin, President of the Board of Trade, stated that he hoped next session to reintroduce the Bill dealing with the testing of thermometers, which was introduced by the Government earlier in the session and abandoned owing to lack of time. Mr. Baldwin also stated that most British manufacturers of clinical thermometers are voluntarily having their products tested at the National Physical Laboratory, where the fee charged for large quantities is *3d.* per instrument, but where any single clinical thermometer can also be tested on payment of a fee of *1s. 6d.* In a circular issued a few days ago by the British Lampblown Scientific Glassware Manufacturers' Association, Ltd., it is pointed out that, whilst makers of good clinical thermometers would naturally depend upon the ordinary course of business to obtain orders solely on quality or make, only rarely do instruments bear the makers' name or trade-mark. The bulk are labelled with "Best British Make," or some similar phrase, and it is very difficult to trace the maker of a faulty instrument. This association of manufacturers

Public Health Services.

NATIONAL INSURANCE IN MANCHESTER.

THE last meeting of the Manchester Insurance Committee as at present constituted was held on Oct. 25th. The Committee was originally instituted in 1912, and its present chairman, Mr. Walter Davies, has served since its inception. He gave an account of the work of the Committee during the nine years of its existence. At first it consisted of 60 members, but under a recent Act of Parliament it will in the future have 35 members only. The number of insured persons in Manchester entitled to medical benefit at October, 1912, was 254,034, and with varying fluctuations it reached 349,441 in October, 1921. The percentage of women in 1912 was 34, and in 1921 had increased to 40. The highest number on the register was 361,278 on April 1st, 1921. About 650,000 medical cards were sent out by the registration department: over 360,000 letters were received and 260,000 were despatched, the number of forms and notices sent out were very large, while personal calls at the Committee's offices reached 220,000. There are now 266 medical men and 150 chemists on the lists of the Committee. By the end of the year the Committee will have contributed nearly £1,000,000 for treatment, while the medical men have provided over 11 million services of all kinds. The cost of prescriptions dispensed—about nine millions—was over £260,000, while over £120,000 had been spent on sanatorium benefit. On a total expenditure of over £1,400,000 the administration cost only amounted to about 5 per cent. There is a balance on the general purposes fund of £8500. A striking feature of the medical benefit service was the very small number of persons who had applied to be allowed to make their own arrangements for medical treatment—out of 350,000 persons treated there were only 61 such cases. Moreover, the number of complaints received was very small considering the number of services rendered. The relations of the medical profession and the Insurance Committee had been completely harmonious, and that happy state of affairs had conduced to an efficient medical service; while at all times the chemists had rendered loyal service. Mr. Davies referred to the encouragement given by the Committee in the matter of nursing, saying it had become a burning question whether nursing should not be absolutely a part of medical benefit. Mr. Davies said in conclusion: "We began our work amidst strong opposition, we have carried on during a period of national upheaval, and we hand over our work to the new Committee with all the services running smoothly, efficiently, and free from grumbles or complaints of any kind. I think this is a record of which we may well be proud."

REPORTS OF MEDICAL OFFICERS OF HEALTH.

HALIFAX.

Dr. J. T. Neech presents his farewell report and reviews the great improvements and changes which have taken place in health matters during his 21 years' tenure of office. Lead poisoning from the water was common at the beginning of this period and has been abolished by adding milk of lime to the water. Dr. Neech has for 12 years been in the habit of disregarding desquamation and discharging uncomplicated scarlet fever cases from hospital after four weeks with eminently satisfactory results as regards return cases. He tells us that cleanliness in the production of milk still leaves much to be desired and that his "council is beginning to awaken to the necessity of replacing the Goux pail by the water-carriage system.

The Registrar-General's estimate of the population of Halifax in 1920 was for death-rate 105,817 and for birth-rate 106,029. The birth-rate was 18·9, the death-rate 13·3, the infant mortality rate 96, and the total tuberculosis rate 0·87. Dr. Neech concludes his report with an article on the need for better ventilation of the home and especially for the open bedroom window, and gives the result of an inspection made in September, 1920, during congenial autumn weather when out of 1419 houses only 498 had open bedroom windows at night.

DERBY.

In his annual report on the health of the county borough of Derby for 1920, Dr. A. E. Brindley tells us that the Registrar-General's estimate is for death-rate 128,868 and for birth-rate 129,220. Some of the important statistics for 1920 are as follows: birth-rate, 25·9; death-rate, 10·8; death-rate from pulmonary tuberculosis, 0·79, and from other tuberculous diseases, 0·13; and the infant mortality rate, 72·7. The death- and infant mortality rates are the lowest, the marriage-rate the highest ever recorded, and the birth-rate is the highest for 13 years. Among unsatisfactory features, Dr. Brindley notes the continued high prevalence of ophthalmia neonatorum and the fact that persons suffering from venereal diseases are under no obligation to continue under treatment till cured or free from infection; to the latter cause he attributes in part the comparatively large number of deaths from premature birth. Good progress is reported in the provision of housing accommodation, 165 houses having been completed and 1420 others begun. A special subcommittee has been concerned with the renovation of existing houses, additional housing inspectors being appointed and a systematic house-to-house inspection initiated. Less progress was made in getting defects remedied when discovered; of 13,809 defects only 2107 could be put right. Improvements were made at the sanatorium, including the provision of a school room for tuberculous children and a workshop for the adult patients, designed to allay discontent among the ex-Service men. Dr. Brindley expresses the hope that maternity and child welfare work will not be curtailed on the grounds of economy, and refers to the increasing usefulness of ante-natal clinics and the valuable help given by voluntary workers.

PORTSMOUTH.

Dr. A. Mearns Fraser is able to present very satisfactory figures in this his twenty-fifth report. He tells us that the death-rate, 11·1, is the lowest ever recorded, and that the infant mortality rate of 60 "is the lowest ever reached in this or any other of the 20 large towns." The civil population is estimated for 1920 at 233,805. The birth-rate was 25·9. The death-rate from tuberculosis of the lungs 0·84, and from other forms of tuberculosis 0·23. The death-rate from diarrhœa and enteritis under 2 years per 1000 living, 0·09, was also the lowest recorded in the 20 large towns. The municipality manufactures and distributes electrolysed sea-water as a disinfectant. One fatal case of tetanus in a baby was recorded, which was traced to the application to the umbilicus of vaseline contaminated by the grey paper washer inserted under the lid of the vaseline pot. Dr. Fraser, in referring to the disappointing results of sanatorium treatment, expresses the fear that the great overcrowding, due to scarcity of housing accommodation will very seriously affect the tuberculosis rate in the large towns. A chart is given showing the remarkable decline in the infant mortality rate from over 170 in 1900 and 60 in 1920, and Dr. Fraser thinks that the Midwives Act of 1902 has been "not the least factor" in this reduction. The net cost of milk, &c., issued to mothers and children under the Order was £970, which does not seem extravagant for a population of nearly a quarter of a million. A municipal maternity hospital, with accommodation for 14 was opened in April, and is intended for patients whose income is under 60*s.* a week. Much work is done under the V.D. scheme. We note that 723 new patients were treated during the year, and that 311 persons ceased to attend either before completing a course of treatment or before a final test as to cure. As is now well known, Portsmouth has adopted the policy of the Society for the Prevention of Venereal Disease, and Dr. Fraser in placing under the control of one medical officer the care of the child before birth, after birth up to five years of age, and during school life, so that preventive measures may be studied and applied in the early years and a minimum amount of work consequently be required later. This ideal has not yet been attained, even in Willesden, because owing to the mass of defects discovered amongst children, and the urgent need for treatment, time has not hitherto been available for the study and application of measures for prevention which should proceed pari passu with treatment. It is obvious that, if and when desired, the Willesden scheme might readily constitute the germ of a public medical service by salaried doctors. Each municipal clinic has its service of doctors, dentists, district nurses, and health visitors, with the use of a municipal hospital and the services of consultants when needed. Domiciliary medical treatment could be added by an increase of the medical staff of the clinic. The public of Willesden appear to like the arrangement.

TURTLE VACCINE.

JUDGING from the interminable discussions in the German medical press since the armistice, Friedmann's remedy still continues to excite interest. The appearance of a critical monograph[1] on the subject is now welcome: it is in the form of a supplement to the *Zeitschrift für Tuberkulose*, one of a series published under the general editorship of Prof. Lydia Rabinowitsch, who has herself recently done some work on the remedy. The stuff, it will be remembered, came before the medical public with a disconcerting flourish of trumpets two or three years before the war, and was then reputed to consist of a vaccine prepared from a living avirulent culture of an acid-fast bacillus isolated from the turtle. Since the war the vaccine is stated by its critics to contain also attenuated human tubercle bacilli. The monograph sets out to investigate carefully the whole question of Friedmann's remedy. A careful analysis is given of the published literature on its value as a means of treatment in tuberculosis. Dr. Ulrici and Dr. Grass have collected records of more than 80 authors, dealing with many hundreds of cases of pleurisy, phthisis, abdominal tuberculosis, meningitis, Addison's and other diseases. In a second section Dr. S. Meyer sets out his investigations into the cultural properties and pathogenicity of the vaccine, with animal experiments designed to test both its protective power as an immunising agent and its curative power in guinea-pigs experimentally infected with bovine and human strains of tubercle bacillus. The conclusions on both counts throw doubt on the value of Friedmann's turtle vaccine.

INTERNATIONAL CONGRESS OF OTOLOGY.

THERE has been no international congress of otology since the meeting in Boston in 1912. The various national committees then appointed have been canvassed and have selected Paris for the tenth congress to be held next year. The cordiality and goodwill of the French Committee towards this country have been marked by a special visit of their secretary-general, Dr. A. Hautant, who came over on purpose to attend the annual dinner of the Section of Otology of the Royal Society of Medicine under the chairmanship of Sir Charles Ballance. He joined in the first meeting of the section on Oct. 21st, when the new President, Dr. Logan Turner, occupied the chair and gave the address which we briefly report on p. 961. Dr. Hautant made the acquaintance of many otologists in London and extended to them and their colleagues a cordial invitation to the congress next summer. A committee of organisation for Great Britain and Ireland has been appointed with Prof. Urban Pritchard as President and Sir StClair Thomson as chairman of the committee and the hon. secretaries are Mr. Lionel Colledge and Mr. J. S. Fraser. No less than 100 otologists have already sent in their adhesion to the committee, and all who are interested are invited to apply to one or other of the hon. secretaries. Those who do so will be kept informed of all the arrangements for the congress as they develop. The office-bearers in Paris are Prof. P. Sébileau (President), Dr. Georges Laurens (treasurer), and Dr. A. Hautant, 28, rue Marbeuf, who is secretary-general. Although the congress remains in name purely otological, it is intended to embrace both rhinology and laryngology. Prof. Sébileau is known not only as an otologist but as a leading exponent of the surgery of the nose, throat, and neck. We are glad to hear that the congress will have a marked practical character, the mornings being devoted to visits to clinics, operating theatres, and museums.

Further details can be obtained from the secretary-general or from the secretaries of the British Organising Committee.

INVOLUTION OF THE UTERUS.

THE conditions that determine the involution of the uterus after parturition are of paramount importance, and they can perhaps be more definitely established in animals than in the human subject. C. Kuramitsu and Leo Loeb have made experiments on rats and guinea-pigs[1] to determine the influence of suckling and castration on this process. The degree of involution was determined quantitatively, and the condition of the whole uterus was compared with that of its individual component tissues. It was found that the process of involution was similar in rats and guinea-pigs, and that sucking accelerated the process; when sucking was suppressed the process was retarded. Castration made it more active. The effects of sucking and castration add to the normal involution changes, and both processes affect all the chief constituents of the uterus, and powerfully influence the growth and structure of the respective tissues. The influence of castration is opposed to that of the suppression of sucking, but when both occur the influence of the former overcomes that of the latter. In guinea-pigs lactation does not interrupt the functional cycle of the ovary and uterus, though it does so in the rat. Sucking or its cessation act indirectly on the uterine tissues. As a corollary to this research, the observers studied the direct effects of lactation on the sexual cycle in the rat and guinea-pig. In the rat ovulation during lactation is inhibited. In the guinea-pig, which suckles its young, ovulation and the normal cycle of changes in the ovary take place. Possibly the corpus luteum functions for a longer time in the rat.

REFRACTIVE CHANGES IN LATER LIFE.

CORRECTION of errors of refraction cannot be properly performed by mechanical rules alone. Even presbyopia needs to be corrected with intelligence, having regard not only to the age of the patient and the purposes for which the glasses are prescribed, but also to the fact that the accommodation of different individuals of the same age varies considerably. The eyes of children frequently undergo considerable changes in the course of their school life, the tendency being for hypermetropia to become less in degree, for low hypermetropia or emmetropia to become myopia, and especially for astigmatism to change from the hypermetropic variety into the mixed and from the mixed into the myopic. It was not, however, of these changes that Mr. Ernest Clarke was speaking in his interesting paper on "Milestones in Refraction Work," read at the Ophthalmological Section of the Royal Society of Medicine and briefly reported last week. There are other refractive changes which take place during mature life. Apart from progressive myopia

Correspondence.

"Audi alteram partem."

THE FLEET STREET WEEK FOR "BART.'S."

To the Editor of THE LANCET.

SIR,—I wish to appeal through your columns to all the many doctors who are ex-Bart.'s men to support our effort for this hospital. Fleet-street devoted the whole of last week to an effort to lessen the great burden of debt which is slowly stifling the activities of the hospital. Over £40,000 have now to be found each year beyond the income of the institution. Add to this a bank overdraft of £25,000 and the position is plain. Many big movements were successfully promoted last week, and if we are strongly supported by all old students of St. Bartholomew's Hospital, and any sympathisers that they can bring, such efforts will be a real help.

Subscriptions will be gratefully received by the Hon. Treasurer, "Fleet Street Week for 'Bart.'s,'" Anderton's Hotel, E.C. 4.

I am, Sir, yours faithfully,
F. H. WILKINSON,
Joint Organising Hon. Secretary.
Oct. 31st, 1921.

"SUNDAY CLOSING" AT BRITISH SPAS.

To the Editor of THE LANCET.

SIR,—I read with much interest the paragraph in your issue of Oct. 22nd, and Dr. Fortescue Fox's letter in to-day's LANCET. I entirely agree with Dr. Fox. I have given mineral baths for many years, and have a personal knowledge of the treatment practised at some foreign and British spas, and I am convinced that a seven-days' week is a drawback in bath treatment, and that a day's rest is of decided benefit once a week at least, and in some cases twice a week. It would be interesting if some of the physicians at our British spas would give their opinions and experiences on this point.

I am, Sir, yours faithfully,
LESLIE THORNE THORNE.
London, Oct. 29th, 1921.

CONTRACT PRACTICE.

To the Editor of THE LANCET.

SIR,—No one will disagree with the statement made by the Federation of Medical and Allied Societies in THE LANCET of Oct. 22nd that many panel doctors give of the best to the service. But how about the majority? It was stated in 1911 that large contract medical work was bad for patient and doctor. Has the profession changed its opinion? If the system is sound why are such large numbers of patients refusing to see insurance doctors, and why in London, out of 7000 names in the Medical Directory, only about 1400 are on the panel? In the *Daily Telegraph* of Oct. 15th, 1921, Sir Dyce Duckworth, referring to the panel system, is stated to have said, "That it had resulted in general failure and had tended to lower the public respect for worthy practitioners. . . . The medical profession had been placed in bureaucratic hands, whose tyranny was injurious to its honour, its independence, and its dignity." In the Hearts of Oak *Journal* for October, 1921, a writer stated that in his district 25,000 out of 125,000 insured persons had not chosen their panel doctor. A writer in the *Daily Mail* some time back informed us that 500,000 insurance persons had refused the same "benefit," and if one takes into account the large number of patients who, although they have panel cards, never go near a panel doctor, the number must be millions.

I am, Sir, yours faithfully,
E. H. WORTH.
Streatham, S.W., Oct. 29th, 1921.

NATIONAL PROVIDENT SCHEME.

To the Editor of THE LANCET.

SIR,—It is now announced in the daily press that there is a great middle-class rush to enrol in the above scheme, through which hospital doctors are to be had for £1 a year. Four general hospitals in London are named as having joined in the scheme. As regards one of them—the Hampstead General and North-West London Hospital—it may be of interest to state that the Medical Committee, after careful consideration of the working arrangements (prospectus dated September, 1921), have informed their board of management of their unanimous decision that the members of the honorary medical and surgical staff are not prepared to take any part in the working of the scheme. A majority of the medical committees of the London general hospitals seem to have acted in the same way, and to have been supported by their governing boards. It is difficult to see how the medical staff of any hospital can retain the title of honorary and at the same time become the paid servants of a commercial insurance company which buys their hospital time and services.

I am, Sir, yours faithfully,
G. A. SUTHERLAND,
Senior Physician to the Hampstead General Hospital.
Oct. 31st, 1921.

Obituary.

FRANCIS ARTHUR BAINBRIDGE, M.A. CAMB., M.D., D.Sc., F.R.C.P. LOND., F.R.S.,

PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF LONDON.

BY the premature death of Francis Arthur Bainbridge, at an age when he had hardly reached the fullness of his power, medical science loses a worker who had made substantial contributions to several of its other branches, before he settled down to follow his natural bent as a teacher and investigator in physiology. At one time he had intended to give himself to clinical medicine, though even then he was making important contributions to pure physiology; indeed, his work on the relation between lymph-flow and glandular activity, dating from this period, is perhaps the most clearly finished of his investigations. Later he turned for a time to general pathology, holding for some years the Gordon lectureship at Guy's Hospital. For a further period he was on the bacteriological staff of the Lister Institute, and several publications on the food-poisoning group of bacteria form a record of sound work in this department of experimental medicine. His real chance, to follow the line of his most genuine inclination, came with his appointment to the chair of physiology at Newcastle. Here he began a valuable series of investigations on the mechanisms coördinating the activities of the heart and the respiratory centre, which he continued after his return to St. Bartholomew's to the chair of physiology there, and which he had still in hand to the end. His own personal contact with these problems, and the wide and critical knowledge of the literature which he acquired in their pursuit, gave a high value to the monograph on "The Physiology of Muscular Exercise," which he published at the end of 1919, and which met with warm appreciation from all who could value its sound and scholarly qualities. As a teacher he was conscientious and increasingly successful, and gave evidence of the high standard which he achieved, to a wider circle than that of his own immediate pupils, in the well-known student's Text-Book of Physiology, which he wrote in collaboration with his colleague at Newcastle, the late Prof. J. A. Menzies. The loss of these two, in the space of a few months, is a loss which the teaching of physiology in this country will find very difficult to make good.

The following appreciation of Bainbridge has been written for us by one with the very best opportunities of knowing him as he was.

THE OUTPUT OF RESEARCH PLACES IN THE UNITED KINGDOM.

BY A. D. WALLER, M.D. ABERD.

(From the Physiological Laboratory, University of London.)

MEASURE of the efficiency of a machine is afforded by its output of energy per unit of energy by which it is fed. We are organising new machinery for the acquisition of fresh knowledge by scientific and industrial and medical research; it will obviously be important to measure the efficiency of such machinery, old and new, and projected. At what cost is the yearly harvest of fresh knowledge being produced, and how can the harvest be measured? The chief objective measure of the harvest of new knowledge is afforded by publication in scientific journals; the number of original papers published by scientific laboratories affords measure of the activity of such laboratories, and when taken in ratio with the annual cost, affords measure of their comparative *efficiency* as research factories. It would be impossible for any single person to undertake a numerical survey of the whole field. It is comparatively easy, however, to carry out a rational survey of a limited portion of the field, by enumerating, e.g., the number of contributions from recognised scientific laboratories to their common outlet of publication, in London—i.e., through the Proceedings of the Royal Society.

The table here given represents the outcome of such a limited survey of the field of biological science, inclusive of physiology and pathology as shown by the list of papers published in the Proceedings of the Royal Society during 15 years from the year 1905 (when the division between series *A* and series *B* was first made). Obviously these figures do not afford any measure of the relative efficiency of the several research factories, since no attempt is made to assess "cost of production" in terms of money.

DONATIONS AND BEQUESTS.—The Manchester Royal Infirmary Board at its last meeting acknowledged the receipt of nearly £820 all available for income. A legacy of £300 from the late Mr. John Bardsley, £175 from the late Miss Mary Hardman, and other donations amount to over £280.—The Great Northern Central Hospital has received a grant of £1000 from the executors of the late Mr. Henry Mayer to endow in perpetuity the Julia and Henry Mayer bed at this institution.

THE MOTOR EXHIBITION:

POINTS FOR THE MEDICAL USER.

(FROM OUR OWN CORRESPONDENT.)

THE Fifteenth International Motor Exhibition opens to-day (Friday) at Olympia and the White City, and closes on Nov. 12th. The medical visitor looking for a car will find many from which to select. For the well-to-do colleague there are automobiles costing well into four figures, and alongside them are others priced at from two to five or six hundred pounds. Contrary to what was the case a few years back, this year's Show is marked by the limited number of models produced by the average individual manufacturer. Where once were found half a dozen and more models on a single stage, the average to-day is round about three, resulting in greater concentration on the types made, saving of capital, and reduction in the number of spare parts which have necessarily to be stocked.

A walk round a large number of depôts and factories has resulted in the conclusion that whereas the 1919 exhibition had much to be seen though little that the purchaser could obtain, the 1920 plenty for delivery though not a few lacking in workmanship and quality of material, the 1921 has, as already mentioned, numerous exhibits to suit all purses, and, what is more, cars of excellent construction and good material. The chief points to be noted are that the four-cylinder engine is still the prime favourite, and no doubt rightly so. There are some two-cylinder light cars, and, of course, the opposed air-cooled horizontal engine which is simple and efficient and has advantages in the matter of cheapness of production, though the cylinders are liable after extended use to become oval through bed wear. Detachable cylinder heads, which permit of machined domes, and are therefore less likely to encourage carbon deposit and pre-ignition, with joints which are easily made and permit of ready cleaning of the piston heads, are on the increase. The overhead valve is certainly gaining ground, although more slowly than was expected. The type actuated by the overhead cam seems to be preferable to the complicated rocker and push-rod kind. Water cooling is still the rule, though a novelty in this connexion is the new oil-cooled little Belsize. Four-speed gear boxes are now in the majority, and the final drive is in most cases by spiral bevel, which is both silent and reliable. The efficient worm drive is still a favourite with some makers, and, when made and fitted by a good firm, is undoubtedly hard to beat. Regarding suspension, the half elliptic spring more than holds its own, as does the cantilever. Most cars are now fitted with electric lighting and starting, the British retaining magneto ignition, though the battery type is quite satisfactory and very common on French and American makes.

Apart from mechanical improvements, the Show has other desirable features. Coachbuilders are paying much more attention to the comfort of drivers and of passengers, ample leg room especially being provided, whilst on many cars the seats themselves can be tilted or moved backwards or forwards. What certainly will appeal to the medical profession is the all-weather type of body, such as the Standard people have produced. A moment suffices to convert the open car into a really enclosed vehicle, with panels or curtains which open with the doors. Another point that will appeal to the owner-driver is the increased attention which is being given to the accessibility of working parts. In the past this did not receive nearly as much consideration as it deserved.

The outstanding feature of the Show is the rapid development of the low-powered car, with its consequent economy in the cost of running and upkeep. Many of the 10–12 h.p. cars are quite capable of giving good and efficient service, and will certainly meet the professional demands of the majority of town and country general practitioners.

ABERDEEN UNIVERSITY CLUB DINNER.—The Aberdeen University Club, London, holds its sixty-sixth bi-annual dinner at Gatti's Restaurant, on Thursday, Nov. 17th, at 7.30 P.M. Graduates desirous of attending the dinner or of becoming members of the Club should apply to Dr. W. A. Milligan, 11, Upper Brook-street, London, W.

GARDEN CITIES AND TOWN PLANNING ASSOCIATION.—The second lecture of the series organised by this association on Great Cities of the World will take place at 5.30 P.M. on Thursday, Nov. 10th, at King's College, Strand. Dr. H. P. Berlage, of The Hague, will lecture on Amsterdam, Past and Present. Sir Walter Townley will be in the chair. The lecture will be given in English and tickets can be obtained from the secretary of the association, at 3, Gray's Inn-place, Gray's Inn, London, W.C. 1.

SOCIETY OF M.O.H.'S: TUBERCULOSIS S.W. SUB-GROUP.—At the first meeting of this sub-group, held at Bristol on Oct. 22nd, members attended from Weston-super-Mare, Bristol, Exeter, Barnstaple, Salisbury, Paignton, and Plymouth. Grievances were discussed in connexion with the drawing up of reports to the Ministry of Pensions, with the advertisement of resident appointments in sanatoriums carrying a salary of £500 to £700 per annum, with board and residence, confined to unmarried men, and with the insecurity of tenure of tuberculosis officers. It was agreed to coördinate the work of officers of the group on the effect of marriage, pregnancy, and parturition on tuberculosis. Domiciliary reports from general practitioners were held to be generally valueless. The acting hon. secretary of the sub-group is Dr. F. G. Bushnell, tuberculosis officer for Plymouth.

LITERARY INTELLIGENCE.—Messrs. William Heinemann, Ltd., announce the early appearance of "Surgical Exposure of the Deep-Seated Blood Vessels," by Dr. J. Fiolle and Dr. J. Delmas; "Surgical Treatment of Non-Malignant Affections of the Stomach," by Dr. C. G. Cumston and Dr. Georges Patry; a new and revised second edition of Dr. Thomas D. Luke's "Manual of Physiotherapeutics"; "The Practitioner's Manual of Gynæcology," by Dr. A. G. Magian; "History of Electro-Therapy," by Dr. Hector A. Colwell; "Rickets," by Dr. J. Lawson Dick"; "Influenza," by several authors, edited by Dr. F. G. Crookshank; and "Dosage Tables for Deep Therapy," by Dr. Friedrich Voltz, edited by Dr. Reginald Morton.—The J. B. Lippincott Company announce the following new publications: "Gynecology," by Brooke M. Anspach; a third edition of "Obstetrics," by G. P. Shears and P. F. Williams; a twelfth edition of White and Martin's "Genito-Urinary Surgery," by Edward Martin, B. A. Thomas, and Stirling W. Moorehead; "Brain Injuries," by William Sharpe; "The Basis of Psychiatry," by Albert C. Buckley; and "Scurvy," by Alfred F. Hess.

ROYAL MEDICAL BENEVOLENT FUND.—Following is a summary of some of the cases relieved at the last meeting of the Committee held on Oct. 11th. The amount voted was £137 to 20 cases.

L.S.A., aged 78, married. Practised in London, but through an epileptic seizure is quite unable to work. His wife has been earning a livelihood as a clerk, but for the past 12 months has had very little to do owing to trade depression, and they have had to sell their belongings to be able to live. The applicant's only income is 10s. per week from the Old Age Pension. Rent 11s. a week. Voted £5 and £26 in 12 instalments.

Daughters, aged 63 and 65 respectively, of M.R.C.S.Eng. who practised in Acton and died in 1902. The younger sister suffers from spinal curvature and requires a lot of attention. Owing to failure of dividends their income has been greatly reduced, and with a friend's help of £22 they only received the total sum of £108. Their rent for two furnished rooms is 30s. per week. Voted £18 in 12 instalments each.

Widow, aged 56, of M.R.C.S. Lond. who practised at Birmingham and died in 1913. Applicant is a trained nurse, and during her late husband's illness took a house as a nursing home. After his death she had to give up the home as her own health broke down, and she went abroad as a companion and unfortunately contracted malaria, and during convalescence discovered that her lungs were affected; she returned to England and received treatment at Midhurst Sanatorium, and lived with her mother until her death. Applicant now asks the Fund for assistance as the pension which her mother received as an officer's widow ceased at her death. She would like to take a country cottage to keep poultry and bees. Voted £18 in 12 instalments.

Widow, aged 69, of L.R.C.P.Edin. who practised in London and died in 1897. Applicant was left totally unprovided for, and owing to old age and infirmity she is entirely dependent on daughter who is the widow of a soldier, and her only income is derived from a pension of £1 6s. 8*d*. per week and what she is able to make by letting. She had a post as a clerk, but this terminated last month. Applicant is asking the Fund for assistance owing to her inability to maintain herself. Voted £26 in 12 instalments.

Widow, aged 35, of M.B.Edin. who practised in Hull and died in May, 1921. Applicant is left totally unprovided for with two small children. Her late husband was only insured for 100, and the majority of this was paid away in funeral and other expenses. At the time of this application she has only £50, and her parents with whom she and her children are now staying are not in a position to continue assistance. Voted £20 in four instalments.

Widow, aged 30, of M.R.C.S. Eng. who practised at Flaxton and died in 1919. Applicant endeavoured to earn a living by shopping on commission and the last 12 months made about £50; she also received £25 from the O.F.F. Applicant and her little daughter are dependent on relatives for a home. Voted £20 in four instalments.

M.B. Edin., aged 71. Practised in Vancouver and Taunton. Through paralysis has had to apply to the Fund for help to pay the fees at the convalescent home connected with the National Hospital, to which he has been sent after receiving treatment. Voted £25 4s. towards convalescent home fees.

Subscriptions may be sent to the Hon. Treasurer, Sir Charters J. Symonds, K.B.E., F.R.C.S., at 11, Chandos-street, Cavendish-square, London, W. 1.

BELFAST UNIVERSITY SERVICES CLUB.—The third annual dinner will be held on Friday, Nov. 11th, 1921, in the Great Hall of the University at 6.45 P.M.

IRISH MEDICAL SCHOOLS AND GRADUATES ASSOCIATION.—The autumn meeting of this association will be held at Pagani's Restaurant, Great Portland-street, London, W., on Thursday, Nov. 17th, at 7 P.M. Members will dine together at 7.30 P.M., Maj.-Gen. W. Wallace Kenny, C.B., taking the chair. Dinner tickets from the hon. sec., Dr. F. Howard Humphris, 8, West Chapel-street, London, W. 1.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH.—A dinner to celebrate the centenary of the Society was held on Oct. 28th in the hall of the Royal College of Surgeons. The chair was taken by Prof. F. M. Caird, the President of the Society. There was an attendance of about one hundred, the company including Sir J. Bland-Sutton, Sir Alfred Ewing, Prof. F. O. Bower, Dr. Byrom Bramwell, Sir James Mackenzie, Dr. George Mackay, Dr. W. K. Hunter, Dr. J. F. Fergus, and Prof. F. J. Charteris. The toast of the King having been honoured, Sir J. Bland-Sutton proposed that of the Medico-Chirurgical Society of Edinburgh, and read a congratulatory message from the Royal Society of Medicine. He referred to the part played by the Society in the cause of medical science, and to the great advances made in all branches of medicine and surgery in recent years. Prof. Caird, in reply, made some interesting references to the early history of the Society. He spoke of the part played by its first President, Dr. Andrew Duncan, senior, in the foundation of the Royal Asylum at Morningside, and reminded the company that the second President was Sir James Young Simpson, and the third, Lord Lister. The Society had proved a mirror of the events passing in the medical world around them, and its members had endeavoured to add their share to the quest of knowledge. The toast of Sister Societies was proposed by Dr. George Mackay, and replied to by Prof. Bower, Dr. Hunter, and Dr. Davidson. Dr. Fergus proposed the toast of the President of the Medico-Chirurgical Society of Edinburgh, and paid a high tribute to the Medical School of Edinburgh, Prof. Caird replying.

ST. THOMAS'S HOSPITAL OLD STUDENTS' ANNUAL DINNER.—A happy re-union of old students of St. Thomas's Hospital and their friends took place at the Wharncliffe Rooms of the Hotel Great Central on Oct. 28th, Dr. H. W. G. Mackenzie presiding. The chairman proposed the toast of the evening, "St. Thomas's Hospital and its Medical School," coupled with the names of the Treasurer, Sir Arthur Stanley, and the Dean of the Medical School, Sir Cuthbert Wallace. He pointed out that the dinner marked the jubilee of the new St. Thomas's Hospital, which had arisen like a phœnix on the banks of the Thames and was opened by Queen Victoria in June, 1871. Dr. Mackenzie traced in brief outline the history of the hospital from the days before the Norman Conquest when a small convent was built on the banks of the Thames by a pious maiden from the proceeds of a ferry over the river, and he passed in review the great names associated with the institution. Dr. Mackenzie referred to the newly-instituted "unit system" as a great success; St. Thomas's, he said, was more than "unit-ed" it was united; for complete harmony existed among the staff, between the staff and the governing body, and, in fact, between all concerned in the organisation and management of the institution. In his reply, Sir Arthur Stanley spoke of the chairman's allusion to Mead, and said that from the time and trouble which that great physician spent on his patients he must have been the forerunner of the panel doctor. Sir Arthur Stanley said that he was an optimist in regard to the financial position of the hospital; he hoped that the money for the students' hostel would be soon forthcoming and that the sports ground at Chiswick would be permanently acquired for the present and future generations. Sir Cuthbert Wallace alluded to the present position of medical education, and spoke of the advantages which might be gained by the correlation of the curriculum of various universities. Dr. R. P. Smith proposed the health of the chairman in felicitous terms, and this was drunk with musical honours.

includes in the present issue a special report which he made to his authority in February. The special report, couched in temperate language, puts forward the case for what has now come to be known as "prophylaxis."

PRESTON.

Dr. F. A. Sharpe was appointed medical officer of health in August, 1920, and refers feelingly to the tremendous difficulty confronting sanitary authorities at the present time—viz., the vast arrears of work to be overtaken with resources depreciated. On the most vital part of public health administration, that dealing directly with the environment of the people, Dr. Sharpe finds that ground was definitely lost in 1920. The health department, he writes, has had to watch with folded hands the steady progress of deterioration in property unchecked by main repairs. Towards the end of the year there was some improvement, but he doubts the ability of private enterprise in the near future to supply the needs of housing. But in spite of a large proportion of the population being unsuitably housed, the absence of epidemics, good climatic conditions, and an improvement in public knowledge each contributed to a favourable year.

The estimated population for birth-rate was 122,133 and for death-rate 121,950. The birth-rate was 24·43, the death-rate was 13·6, the death-rate from pulmonary tuberculosis 0·91, and from non-pulmonary tuberculosis 0·38. The infant mortality rate was 101. In commenting on the milk-supply Dr. Sharpe writes that the high price and poor quality of the milk sold in the county are rendering it an unpopular diet for the children of the wage-earners, contrasting this state of affairs with New York and other cities of the U.S.A., where a determined effort is being made to produce a clean and reliable article, and where the consumption of milk is at least three times greater than in this country. There were 21 cases of ophthalmia neonatorum notified; 18 recovered completely, in one case one eye was lost and the other injured, in two cases both eyes were lost, one of these babies dying at the age of two months.

SWITZERLAND.

(FROM OUR OWN CORRESPONDENT.)

THE RECENT SMALL-POX EPIDEMICS IN BASLE AND ZURICH.

THE epidemics of small-pox in Basle and Zurich have come to an end. In the latter place some 120 cases were recorded with no death, all cases having been of a very mild type. It has even been suggested that it was not small-pox at all. The outbreak at Basle, however, has proved more serious. There were only 47 cases, but 8 deaths. The epidemic has been very closely studied, and Swiss towns, with their stable populations, are a very proper object for the investigation of an epidemic. Some details which are contained in the report of Dr. H. Hunziker, health officer of Basle, may be of interest. The 47 cases included three persons who had left Basle during the incubation period and developed small-pox abroad. One of them could be traced to Berlin. The disease was brought into Basle by a German railway official on service between Basle and Frankfort who had lodgings in a Basle family. He infected his landlord who developed small-pox, which remained undiagnosed, being taken for chicken-pox. The disease was not brought to the notice of the authorities until a friend of this man developed typical small-pox. Four other cases could be traced to the same source. Afterwards it was found that the first man during his disease, which was of the mild type, had helped to pack about 1000 rolls of butter in a dairy-shop, but no cases could be traced to clients of this particular shop. Apart from persons who had contracted the disease by direct contact there remained a considerable number of cases where the source of infection was absolutely obscure. Several of them were known as leading a very secluded life—one was an inmate of an asylum whose whereabouts could be exactly controlled and whose visitors were checked. It was further noticed that all these cases lived within a short radius of the isolation hospital where the small-pox cases were nursed. Dr. Hunziker after careful investigation came to the conclusion that the epidemic in these cases was spread by flies. He corroborates this statement by the following facts. Flies were always found in great number round the small-pox patients; this was noticed in the hot days of July, when there was a great increase of flies. The epidemic subsided when cooler weather set in.

Dr. Hunziker was further able to show that he could, by inoculating the cornea of a rabbit with stuff from flies caught near small-pox patients, obtain a positive result of Paul's reaction. In some cases the incubation period could be observed exactly; it varied from nine to ten days. It was also found that the patients were not infectious during the period of the prodromal symptoms and at the beginning of the rash. Early isolation proved always successful. The age of the small-pox patients varied between 1 and 67 years. Twenty-four cases had never been vaccinated, 16 of them were severe. Eleven cases were vaccinated only once and had never been revaccinated, one being a severe case. Ten cases had been revaccinated, none of them was severe. During the epidemic there was a great rush to the vaccination stations. But there remains still a very large proportion of the population which is unvaccinated. In the cantonal council a motion has been introduced for the adoption of compulsory vaccination. The hope of it being carried, however, is but small.

NATIONAL BABY WEEK COUNCIL.

THE National Baby Week Council held its annual meeting in the Armitage Hall, Great Portland-street, London, on Oct. 25th. Lord Astor, who presided, said that while everybody was talking of economy it was useless to think that economic problems could be solved on any other basis than that of an intelligent understanding of the issues involved. Real economy was not achieved by an indiscriminate reduction of expenditure; a nation which wisely regarded its children as its greatest asset would realise the false economy of unreasonably reducing its output on their behalf. The work of the Council was not confined to the saving of life, but included also the prevention and reduction of incapacity with its inevitable financial burden. Dr. W. Allen Daley, medical officer of health for Blackburn, read a paper on the Economic Value of Maternity and Child Welfare Work, emphasising at the outset the importance of having all the facts in our possession, in order that we may put before the public a convincing statement as to what child welfare work is, and what it does. People who regarded a high infant mortality-rate as a convenient means of weeding out the unfit were wrong; a high death-rate among infants was almost invariably associated with a high damage-rate, many children being allowed to become and to remain unfit. An example of the result of public health work was furnished by the borough of Kensington, which included among its inhabitants two extremes of social class. By means of special work undertaken by the medical officer of health, including the appointment of 15 health visitors for the north, as against 4 for the south, the infantile mortality-rate was lower in North than in South Kensington in 1920 for the first time. The average expenditure on public health work in 1919–20 had been at the rate of 5*s.* 3*d.* per head, of which 1*s.* 4*d.* was spent on treatment for infectious diseases, 1*s.* 7*d.* on tuberculosis, 8*d.* on maternity and child welfare, 3*d.* on venereal disease, 6*d.* on school medical service, and 11*d.* on general administration, inspection, and so forth. Dr. Daley considered that the cost of infectious diseases might be reduced by nursing mild cases of scarlet fever at home instead of in hospitals, a point which was taken up by Major C. P. Lovelock, whose experience was that scarlet fever could be quite satisfactorily isolated in the home without risk of spreading infection. The annual report and balance sheet were unanimously adopted; Mrs. H. B. Irving and Dr. E. Sloan Chesser were re-elected as joint hon. secretaries and Mr. James Marsden as hon. treasurer, with the addition of Mr. Henry Higgs as co-treasurer with Mr. Marsden.

lunatic asylums, and whether the supervision of female lunatics was conducted by men or by women.—Sir A. MOND replied: The answer to the first part of the question is in the affirmative. As regards the second part all the attendants and nurses for female patients are women.

Proposed Registration of Herbalists.

Lieut.-Commander KENWORTHY asked the Minister of Health whether His Majesty's Government contemplated any steps for the better regulation and registration of herbalists on the lines of the recent Dentists Act.—Sir A. MOND replied: The answer is in the negative.

FRIDAY, OCT. 28TH.

Lapsed Insurance Contributions.

Sir A. MOND (Minister of Health), in moving the second reading of the National Health Insurance (Prolongation of Insurance) Bill, explained that its object was to keep in benefit a large section of contributors to Approved Societies who, owing to unemployment, had lapsed. The subscribers would be credited with contributions for a certain number of weeks, the cost falling on the Approved Societies. There would be no charge on the State.

The Bill was read a second time.

MONDAY, OCT. 31ST.

The Territorial Voluntary Aid Detachment.

Lieut.-Colonel PINKHAM asked the Secretary for War what progress was being made with the Territorial Voluntary Aid Detachment scheme: how soon would the actual conditions of service and establishment be determined; and was he aware that at the present moment the existing detachments were rapidly dwindling, whilst others had been or were being disbanded owing to lack of any definite rules and regulations, the temporary rules sent out not meeting the case.—Sir LAMING WORTHINGTON EVANS replied: The Army Council have approved the principles of a new scheme, the details of which are to be considered by a committee on which the British Red Cross Society and other authorities concerned will be represented. In regard to the last part of the question, so far as I am aware there has been since Jan. 1st last a net reduction of 21 detachments only out of a total of 4037.

Taxation of Lactose.

Mr. LAMBERT asked the President of the Board of Trade why, seeing that the Board of Trade under the Safeguarding of Industries Act was not permitted to tax food, lactose or milk sugar, an important ingredient in the manufacture of infant food, had been scheduled for taxation.—Mr. BALDWIN replied: Articles of food or drink are expressly excepted only from the operation of Part II. of the Safeguarding of Industries Act, and not from Part I., under which lactose of a certain grade and purity is dutiable.

Proposed Drawback on Hospital Chemicals.

Dr. MURRAY asked the President of the Board of Trade whether he was aware that a large number of proprietary articles of continental origin included in the Key Industries Schedule of the Safeguarding of Industries Act were used by hospitals, and that, owing to the duty now imposed, these hospitals would have to pay much higher prices; and whether he was prepared to allow a drawback to these hospitals on such medical chemicals, in view of the low state of the finances of these institutions.—Mr. STANLEY BALDWIN replied: A number of the commodities covered by the general chemical heading of the schedule to the Safeguarding of Industries Act are, no doubt, of the kind stated by the hon. Member. The experience of the war years showed, however, the grave danger of dependence upon foreign sources for important medical supplies, and the need of action to prevent so far as possible its recurrence; and I am not prepared to introduce the legislation necessary to give effect to the hon. Member's suggestion.

The Government Grant to Voluntary Hospitals.

Mr. LEONARD LYLE asked the Minister of Health whether the Government still adhered to its promise, arising out of the Cave Committee's Report, to allocate £500,000 to the voluntary hospitals; what steps in that case had been taken towards the allocation of the fund; within what period was it intended it should be allocated; and whether in each case a stipulation was to be attached to the effect that before a hospital could receive a grant it must put up a sum equal to the grant made up of new money.—Sir A. MOND replied: The grant of £500,000 towards the liquidation of the voluntary hospital deficits was voted by the House last August. The Voluntary Hospitals Commission are taking steps to establish local hospital committees on the lines recommended in Lord Cave's Report, and it is hoped that the personnel of a number of these committees ill be complete within the next few weeks. King Edward's und, who act as the local committee for London, have de considerable progress with their work, and emergency nts will be distributed at an early date to the most necessitous of the metropolitan hospitals. I am informed that it is not anticipated that the full amount of the grant will be spent during the current financial year, and an estimate will be submitted to the House next session for a re-vote of the unexpended balance. As regards the conditions attaching to the grant I would refer my hon. friend to the White Paper (Cmd. 1402) which was circulated in July.

The Spahlinger Treatment of Tuberculosis.

Sir CLEMENT KINLOCH-COOKE asked the Minister of Health whether any further investigation had been made in the matter of the Spahlinger treatment for tuberculosis; and when it was likely the treatment would be available for patients suffering from this disease.—Sir A. MOND replied: I understand that certain unofficial investigations have been made in this matter, but that no definite conclusions have been arrived at. As I have already stated, it will not be possible to undertake any independent investigation as to the efficacy of the Spahlinger treatment which is essential in a matter of this importance until supplies of the serum are available in this country. I understand that such supplies are not yet forthcoming.

TUESDAY, NOV. 1ST.

Ex-soldiers and Tuberculosis.

Mr. SITCH asked the Minister of Pensions the number of applications for pensions received from ex-soldiers suffering from tuberculosis; the number of awards conferred on cases of such disability certified as resulting from service with His Majesty's forces; and the number of cases of tuberculosis not so certified or accepted as being due to service during the war.—Major TRYON replied: The records of the Ministry are not kept in such form as to enable a complete answer to be given to this question without a very considerable amount of research which my right hon. friend is not prepared to impose on his staff. I can, however, inform my hon. friend that during the past 18 months 6500 awards were made in respect of tuberculosis; but as rejections are not classified according to diseases, I am unable to state the number of claims in respect of tuberculosis which were not accepted during that period.

The Services.

ROYAL ARMY MEDICAL CORPS.

Temp. Capt. J. A. Marsden to be temp. Maj. whilst empld. as Dep. Asst. Dir. of Hygiene.

Capt. J. E. Brooks is secd. for service under the Colonial Office.

Capt. T. Young relinquishes the actg. rank of Maj.

The undermentioned temp. Capts. relinquish their commns., and retain the rank of Capt.: R. E. Smith and J. M. Browne.

Capt. W. McM. Chesney retires receiving a gratuity, and is granted the rank of Maj.

2nd Life Guards.—Surg. Lt.-Col. J. H. Power retires on ret. pay.

ARMY DENTAL CORPS.

Capt. D. Blair to be Maj.

Temp. Capt. A. McCormack, Dental Surg., from Spec. List, to be Lt., and to be temp. Capt.

OVERSEA FORCES.

S. Afr. Med. Corps.—Temp. Capt. L. W. Blazey, Dental Surg., relinquishes his commn. on completion of service, and retains the rank of Capt.

REGULAR ARMY RESERVE OF OFFICERS.

The undermentioned, having attained the age limit of liability to recall, cease to belong to the Res. of Officers:—

Army Medical Service.

Maj.-Gens.: Sir W. W. Pike, Sir H. N. Thompson, L. E. Anderson, S. Macdonald, and W. T. Swan.

Cols.: A. J. Luther, C. W. R. Healy, F. W. Begbie, S. F. Clark, W. L. Gray, and H. N. Dunn.

Royal Army Medical Corps.

Lt.-Cols.: N. Tyacke, C. A. Stone, H. W. H. O'Reilly, and D. Lawson.

Majs.: A. Pearse, Bt. Lt.-Col. F. J. Brown, R. F. E. Austin, and T. J. Lenehan.

Capt. J. M. Darling to be Maj.

TERRITORIAL ARMY.

Maj. (Bt. Lt.-Col.) E. S. Forde resigns his commn. and retains his rank with permission to wear the prescribed uniform.

Majs. W. H. Rowell and J. D. C. Swan resign their commns. and retain the rank of Maj.

"To those of us who, knowing him intimately, could appreciate the fine qualities of his brain and his character, it seemed that he came rather late to the full recognition which he deserved. His early tendency to diffuse his interests had some part in this, and his career was not without its discouragements, met with a quiet persistence which was characteristic and admirable. His physique, his voice, his quiet manner, were not such as easily command attention, and in presenting his own work to his colleagues he had not, at first, that gift of vividness which strikes the imagination. Yet by quiet determination and conscientious work he made himself an unusually successful teacher of his subject, and caution and reticence had their own reward in the sincere and growing respect with which his work, his knowledge, and his judgment were regarded by his fellow physiologists.

There are many, without as well as within the circle of physiologists, who will mourn the loss not only of a valued colleague, but of a dear and staunch friend. To the writer this sense of a double loss comes with a peculiar intensity. A personal intimacy and scientific comradeship, beginning when, as boys at school, we started to read Foster's Physiology together, lasted unbroken through student days at the same college and the same hospital, and survived all minor separations of domicile or of interest to the end. This loyalty was an outstanding quality of Bainbridge's character. In a circle of widening friendships, he kept and cherished those of his boyhood and youth as few men do. A friend to both of us from Cambridge days writes to me, very truly, that 'Bainbridge was one of the exceedingly few people in whose case a long absence was merely a temporary gap, not a separation and a change.' Family affection and early friendship struck very deep roots in a character which was quiet, reserved, and firm, rather than facile and enthusiastic. During the last few years ill-health had made sad inroads on his time and his strength. He chafed at the enforced interruption of his work, but looked to the future with quiet courage and determination. To his widow, gallant comrade in his success and in his losing fight with physical adversity, to his sisters and his young daughter, will go out the sympathy of all who had come to know and honour his steel-true character; and science will be the poorer for the cutting short of a career, which still showed as much of promise as of achievement."

FREDERIC THORNE, M.D. ST. AND., M.R.C.P. LOND.

Dr. Frederic Thorne, who died at Adderbury East, Banbury, on Oct. 16th, in his seventy-sixth year, was a younger brother of the late Sir Richard Thorne-Thorne, sometime principal medical officer to the Local Government Board. Like him, he received his medical education at St. Bartholomew's Hospital, qualifying M.R.C.S.Eng. in 1869, and becoming later M.R.C.P.Lond. and M.D. St. And. His professional career began with 20 years of general practice at Leamington, followed by consulting work—he was on the staff of the Midland Counties Home for Incurables—from which he retired ten years ago, entering then with great activity into public life. He was elected a member of the Banbury rural district council in 1911, and held various offices on that body, including that of chairman of the public health committee. In his early days he had held a commission in the Warwickshire Volunteers, and after the outbreak of war, when the Volunteer Force was formed, he took over command of the Banbury Company in spite of indifferent health. Under his guidance the company grew in strength and efficiency and when it became absorbed into the general military system he was appointed a Captain in the Oxford and Bucks Light Infantry, to which his battalion had been affiliated. For the past two years he had suffered from an internal malady and his death, which is mourned by a wide circle of friends, was not unexpected. Dr. Thorne was thrice married, one of his sons being Dr. James Thorne of Edinburgh.

CHARING CROSS HOSPITAL: A NEW WARD.—The new ward at Charing Cross Hospital, which was dedicated by Princess Louise, Duchess of Argyll last month, owes its inception to the Shanghai Race Club which, during the war, continued racing and devoted the proceeds to charitable purposes. By the end of 1920 the Club had distributed something in the neighbourhood of £120,000. The new ward has been endowed with a sum of £12,000, and the stewards have undertaken to make what contributions they can towards its upkeep.

Medical News.

UNIVERSITY OF CAMBRIDGE.—The following degrees have been conferred:—

M.B. and B.Ch.—L. W. Jones, Emmanuel.
M.B.—L. P. Garrod, King's; H. H. Brown, Caius.

CAMBRIDGE TUBERCULOSIS COURSE.—A course of lectures, demonstrations, and practical work on the pathology, diagnosis, and treatment of tuberculosis, with special reference to administrative measures for dealing with the disease, is being arranged for the month Nov. 14th to Dec. 17th, at the Medical School, Cambridge, and the Papworth Colony. Further details in our advertisement columns.

MEDICO-LEGAL SOCIETY.—A meeting of this Society will be held at 11, Chandos-street, London, W., on Tuesday, Nov. 15th, at 8.30 P.M., when a paper will be read by Dr. Thomas Good on Nature *versus* Law, with special reference to the development of psychotherapy and its problematical use in the treatment of feeble-minded persons and criminals. The annual dinner will be held on Wednesday, Dec. 14th, instead of as previously announced. Further particulars will be announced shortly.

ROYAL SOCIETY.—The President and Council wish to continue the collection of engravings and photographs of Fellows in their possession on the lines which have been adopted by the trustees of the National Portrait Gallery—namely, by photographs uniform in size and character, which will be stored and catalogued. Arrangements have been made with Messrs. Russell and Sons, 73, Baker-street, London, W., by which they will take a photograph (by appointment) of any Fellow, free of charge, and deposit a copy with the Society. Those Fellows who have not within the last two or three years given a sitting to Messrs. Russell are asked to assist in making the collection complete by arranging for a sitting as soon as possible.

HOSPITAL SATURDAY IN MANCHESTER: A SECOND APPEAL.—During last week a second and special collection in aid of the Hospital Saturday Fund was made in places of business, factories, workshops, and warehouses in Manchester and Salford. The second appeal was made because in June last—the usual time for the appeal—many sources of income were closed on account of the coal dispute. The response was, in fact, £1000 short of the contributions of the previous year. In Manchester, as elsewhere, the hospitals are faced with a falling income. At the Ancoats Hospital during the last nine months the expenditure exceeded the income by over £3000. In past years the people of Manchester do not appear to have subscribed to their own hospitals to nearly the same extent as other large towns do. Last year the 21 local hospitals provided treatment for 36,040 in-patients, 343,344 out-patients, 20,821 home patients, and 61,217 sufferers from accidents—a total of 465,023 cases. There are also two convalescent homes for workers, one at Deganwy, in North Wales, with 50 beds, and one at Arnside, with 31 beds for women only.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary Comitia was held on Oct. 27th, Sir Norman Moore, the President, being in the chair. It was announced that Mr. Ronald Henry Knight had been elected as the twenty-ninth Jenks scholar.—Dr. A. J. Cleveland and Dr. F. H. Jacob, elected at a previous meeting, were admitted to the Fellowship.—The following were admitted to the Membership of the College: Dr. J. R. Bell, Dr. W. H. Best, Dr. R. E. Collins, Dr. G. C. Linder, Dr. A. G. Maitland-Jones, Dr. W. E. Waller, Dr. P. H. Wells.—Licences to practise physic were granted to 77 candidates who had passed the necessary examinations.—Dr. Sidney P. Phillips and Dr. G. F. Still were nominated by the President to serve on a committee called together by the College of Preceptors to consider the physical education of girls.—Dr. M. K. Robertson was granted permission to resign his membership of the College.—The application of Dr. J. J. Macwhirter Dunbar for restoration of his membership resigned in 1881 was read a second time.—Prof. C. S. Gibson was appointed an examiner in chemistry in place of Dr. Le Sueur, deceased.—A committee was appointed to consider changes in the curriculum and examination for the Conjoint Diploma, consisting of the President and Registrar ex officio, Sir William Hale-White, Sir H. D. Rolleston, Sir James Galloway, Dr. H. M. Fletcher, Dr. G. F. Blacker, and Sir John Broadbent.—The High School for Girls, Wimbledon, was recognised for instruction in chemistry, physics, and biology.—Sir William Hale-White was re-elected a member of the Committee of Management.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, Marylebone, W.
MONDAY, Nov. 7.—11 A.M., Dr. Goodall: Out-patients. 2 P.M., Dr. Moon: In-patients. 5.30 P.M., Lecture:—Dr. J. S. Goodall: Extra Systoles and their Significance.
TUESDAY.—10 A.M., Dr. Parsons-Smith: Out-patients. 10 A.M., Dr. Price: In-patients. 2 P.M., Sir S. Russell-Wells: Out-patients.
WEDNESDAY.—10 A.M., Dr. Parkinson, and 2 P.M., Dr. Moon: Out-patients.
THURSDAY.—2 P.M., Dr. Price: Out-patients. Dr. Moon: In-patients. 6.30 P.M., Dr. Hamill: Out-patients.
FRIDAY.—10 A.M., Dr. Parsons-Smith: Out-patients 2 P.M., Dr. Parkinson: Out-patients. 3 P.M., Dr. Parkinson: In-patients. 4 P.M., Dr. Goodall: In-patients.
SATURDAY.—10.30 A.M., Dr. Hamill: In-patients.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Nov. 10th.—4 P.M., Lecture:—Mr. L. E. Barrington-Ward: The Management of Acute Abdominal Conditions.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.
THURSDAY, Nov. 10th.—6 P.M., Chesterfield Lecture:—Dr. J. L. Bunch: Pruritus and Itching Diseases of the Skin.

ST. MARYLEBONE GENERAL DISPENSARY, 77, Welbeck-street, Cavendish-square, W.
Post-Graduate Course on Infant and Child Welfare.
A Course of Twelve Lectures on the Management and Feeding of Infants and Young Children, by Dr. E. Pritchard, to Qualified Practitioners.
WEDNESDAY, Nov. 9th.—6 P.M., Lecture XI.:—Rickets, Causes, Symptoms, and Treatment.
FRIDAY.—6 P.M., Lecture XII.:—The Feeding of Children between Nine Months and Two Years.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.
TUESDAY, Nov. 8th.—4.30 P.M., Mr. W. F. Shaw: Urinary Symptoms in Gynæcology.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURES, Whitworth-street, West Branch, Manchester.
FRIDAY, Nov. 11th.—4.30 P.M., Dr. Fothergill: Pelvic Varicocele.

ANCOATS HOSPITAL.
THURSDAY, Nov. 10th.—4.30 P.M., Dr. G. Langley: The Significance and Treatment of the Irregular Pulse.

UNIVERSITY OF SHEFFIELD.—FACULTY OF MEDICINE.
Post-Graduate Lectures and Demonstrations.
TUESDAY, Nov. 8th. (At the Jessop Hospital).—3.30 P.M., Mr. W. W. King: Demonstration of Gynæcological Cases.
FRIDAY. (At the Jessop Hospital).—3.30 P.M., Prof. M. H. Phillips: Demonstration of Gynæcological Cases.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.
A Course of Eight Lectures and Discussions on Problems of Public Health in Relation to Industrial Hygiene at the Lecture Theatre of the Institute.
WEDNESDAY, Nov. 9th.—4 P.M., Lecture IV.: Prof. L. McIlroy: The Problem of the Working Mother.

Appointments

Borthwick, G. A., M.B., Ch.B. Edin., has been appointed Assistant Medical Officer of Health and Assistant School Medical Officer for Barnsley.

Simpson, Keir, M.D., Ch.B. Edin., D.P.H., Deputy Medical Officer of Health and School Medical Officer for Croydon.

Certifying Surgeons under the Factory and Workshop Acts.—**Dwyer, M.**, L.R.C.P.Lond., M.R.C.S.(Tattenhall): **Allan, J. G.**, M.B., Ch.B.Edin. (Catrine): **Wall, D.**, M.B., Ch.B. Edin. (Hoo, Kent); **Pirie, A. W. R.**, M.B., Ch.B.Aberd. (Preston).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen, Royal Hospital for Sick Children.—Hon. S.
Bedford County Hospital.—Asst. H.S. £150.
Birkenhead Borough Hospital.—Jun. H.S. £200.
Bristol General Hospital.—Cas. H.S. £175.
Bury Infirmary.—Junior H.S. £150.
Camberwell Infirmary.—Jun. Asst. M.O. £350.
Cambridge, John Bonnett Clinical Laboratory.—Clin. Path. £300.
Cape Town University.—Lectureships. £150 and £400.
Cardiff, University of South Wales and Monmouthshire.—Lecturer in Path. and Bact. £750.
City of London Hospital for Diseases of the Chest.—Half-time M.O.
Coulsdon, Netherne Mental Hospital.—Two Asst. M.O.'s. £400 to £500.
Dumfries, Crichton Royal Mental Hospital.—Clin. Pathologist. £400.
Durham County Council.—Asst. Welfare M.O. £600.
East London Hospital for Children, &c., Shadwell, E.—H.S. £125.
Epsom Manor Certified Institution.—Asst. M.O. £400.
Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Asst. H.S. £150.
Great Northern Central Hospital, Holloway-road, N.—Two P.'s.
Grimsby and District Hospital.—R.H.S. £300.
Hull Royal Infirmary.—Hon. Pathologist.
Kensington Dispensary and Children's Hospital, 49, Church-street, W.—Hon. Dent. S.
Kensington and Fulham Hospital. Hon. P.
London Fever Hospital, Islington, N.—Res. M.O. £500.
Manchester Royal Infirmary.—Res. M.O. £250.
Manchester, St. Mary's Hospitals for Women, &c.—Two H.S.'s. Each £100.
Middlesbrough, North Riding Infirmary.—Sen. H.S. and Jun. H.S. £200 and £150.
Mothers' Hospital, Lower Clapton-road, E.—Res. M.O.
Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £200.
Nottingham General Hospital.—H.S. £200.
Portsmouth Royal Hospital.—Third H.S. £150.
Queen Charlotte's Lying-in Hospital, Marylebone-road, N.W.—Sen. Res. M.O. £100. Asst. Res. M.O. £60. District Res. M.O. £80.
Royal Dental Hospital, Leicester-square.—House Anæsth. 10*s.* 6*d.* each Attendance.
Royal Eye Hospital, St. George's Circus, Southwark, S.E.—Hon. Asst. S.
Royal Naval Medical Service.—Surg. Lieuts.
Royal Sea Bathing Hospital, Margate.—S. £200.
St. Mary's Hospital, Paddington.—Med. Supt. £350.
South Eastern Hospital for Children, Sydenham, S.E.—Res. M.O. £100.
Sunderland Royal Infirmary.—H.S. £200.
Ventnor, Royal National Hospital for Consumption.—Asst. Res. M.O. £300.
Virginia Water, Surrey, Holloway Sanatorium.—Jun. Asst. M.O. £400.
Warwickshire County Council.—Asst. M.O.H. £550.
West London Hospital, Hammersmith-road, W.—Hon. Surg. Registrar.
Western Ophthalmic Hospital, Marylebone-road.—Hon. Radiologist amd Hon. Asst. Anæsth.
Winchester, Royal Hampshire County Hospital.—H.S. £150.
Wokingham, Berks, Pinewood.—Med. Supt. £600.
Worcester General Infirmary.—Res. M.O. £200.

Births, Marriages, and Deaths.

BIRTHS.

Bernard.—On Oct. 24th, at Lower Stone-street, Maidstone, the wife of Dr. E. A Bernard, of a daughter.

Fenton.—On Oct. 24th, at Farfield House, Kidderminster, the wife of V. N. Fenton, M.B., B.Ch.Cantab., of a son.

Smalley.—On Oct. 29th, at a nursing home, Manchester, the wife of Major J. Smalley, I.M.S., of a son.

MARRIAGES.

Morton—Dobie.—On Oct. 24th, in London, Flight-Lieut. T. C. Morton, M.B., D.T.M., R.A.F.M.S., to Emily Frances, eldest daughter of D. Robertson Dobie, M.D., F.R.C.S., Crieff, Scotland.

DEATHS.

Bainbridge.—On Oct. 27th, at Clarence Gate-gardens, Regent's Park, Dr. Francis Arthur Bainbridge, F.R.S., F.R.C.P., aged 47 years.

Beaumont.—On Oct. 28th, suddenly, at Charing Cross Hospital, Edgar Beaumont, M.D., of Montague House, Upper Norwood.

Brockatt.—On Oct. 24th, in London, Andrew Alexander Brockatt, M.D., lately of Great Malvern, in his 58th year.

Gardiner.—On Oct. 28th, suddenly, at his residence, the Old Court House, Richmond, Surrey, Matthew Henry Gardiner, M.B., C.M. (Edin.), aged 64 years.

Rolston.—On Oct. 27th, at Glen Maye, Yelverton, Devon, George Theodotus Rolston, J.P., L.R.C.S., L.S.A., late of Stoke, Devonport, aged 91 years.

Wickham Legg.—On Oct. 28th, at Woodstock-road, Oxford, John Wickham Legg, Hon. D.Litt. Oxon., F.R.C.P. Lond., aged 77 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Presentation to a Medical Man.—Dr. T. P. Stewart, of Newport, Fifeshire, has recently been presented with a complimentary letter bearing the names of 600 friends and patients, as well as a silver salver and a cheque for £1400, "as a token of affectionate regard and grateful thanks for his 31 years skilful, generous, and self-sacrificing service."

Warneford Hospital, Leamington.—The new out-patients wing of this hospital, erected at a cost of £25,000, was opened on Oct. 26th by Princess Helena Victoria. Dr. Bernard Rice, consulting surgeon to the hospital, said that last year there were 37,000 attendances in the out-patient department, and although the hospital had been losing something like £2000 a year the committee felt that they must maintain a hospital which had existed on a voluntary basis for 90 years. At the reception held in the afternoon purses were received containing about £2500.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Unemployment and Health Insurance.

A BILL was introduced by Sir ALFRED MOND, Minister of Health, and read for the first time on Wednesday, Oct. 26th, entitled the National Health Insurance (Prolongation of Insurance) Bill. The measure extends temporarily the period during which persons who are unemployed may remain insured under the general provisions of the National Health Assurance Acts, 1911 to 1921.

HOUSE OF COMMONS.

WEDNESDAY, OCT. 26TH.

The Demolition of Slum Areas.

Major BARNES asked the Minister of Health whether any schemes had come before the Ministry for the demolition of slum areas in respect of which a special grant had been offered by the Government in the current year.—Sir A. MOND replied: In view of the necessity of concentration on the production of new houses, comparatively few proposals for the demolition of slum areas have been submitted. Definite schemes have been received in respect of 19 areas, while in a number of other cases informal proposals have been discussed with the local authorities. Four schemes have been confirmed or confirmation promised, of which one is the Brady-street scheme of the London County Council.

Infant Death-rates.

Dr. ADDISON asked the Minister of Health what the infant death-rate for London had been for each quarter of the present year up to the end of September, and what had been the corresponding rates for England and Wales.—Sir A. MOND replied: According to the Registrar-General's returns the figures are as follows:—

Deaths under 1 per 1000 Births, 1921.

	London.	England and Wales.
1st quarter	85	101
2nd ,,	59	67
3rd ,,	93	83

The excess of the London rate over the rate for England and Wales in the third quarter is mainly due to infantile diarrhœa which has, of course, a heavier incidence in towns than in the country as a whole.

Pure Lactose and Safeguarding of Industries Act.

Mr. LAMBERT asked the President of the Board of Trade if lactose is a dutiable article under the Safeguarding of Industries Act; if so, was he aware that lactose was used to prepare in this country reliable infant foods; and whether, in view of pledges given that food should not be taxed for what reason, since infant food manufactured abroad could be imported free, was the manufacturer of infant food in this country to be penalised by the taxation of an important ingredient in his product.—Mr. BRIDGEMAN replied: Crude lactose is not dutiable, but the purer qualities, such as those which fulfil the requirements of the British Pharmacopœia, are held to be dutiable under the Safeguarding of Industries Act, under the general heading of Fine Chemicals. I am aware that the purer qualities are used for the purpose described by my right hon. friend. The Board of Trade have no power to exclude on any ground from the operation of the Act any commodity properly included within the general headings of the Schedule. The question as to whether lactose is properly so included is a matter which can be referred to the referee to be appointed under Section I. (5) of the Act, and a complaint on the point is being referred accordingly.

Deaths from Disease in Mesopotamia.

Sir THOMAS POLSON asked the Secretary of State for the Colonies how many deaths from disease had occurred during the last six months among officers and men of the British forces stationed in Mesopotamia.—Mr. CHURCHILL replied: The figures are as follows: British forces under the War Office, 56; British forces under the Air Ministry, 7; Total deaths from disease, 63.

THURSDAY, OCT. 27TH.

Ex-Service Men in Lunatic Asylums.

Captain LOSEBY asked the Minister of Pensions the number of ex-Service men at present confined in lunatic asylums who were in receipt of treatment allowances.—Major TRYON replied: The number of ex-Service men classified as Service patients in respect of whom treatment allowances are paid or credited is 6135.

Tuberculous Gland Treatment by X Rays.

Lieut.-Colonel DALRYMPLE WHITE asked the President of the Board of Education whether, in view of the great superiority of the treatment of tuberculous glands by X rays over the former surgical treatment, he would reconsider his decision not to sanction any further treatment by X rays, at all events in such localities where there was a general hospital with X ray installation.—Mr. FISHER replied: I presume that the hon. and gallant Member has in view the limited experiment at Southport in this form of treatment which the Board sanctioned in October, 1919. I am advised that the results of that experiment are not such as to justify the Board in entertaining at present proposals for further expenditure on the continuance or extension of the experiment.

Appointments at Holloway Convicted Hospital.

Lieut.-Colonel Sir SAMUEL HOARE asked the Secretary for the Home Department whether a wardress with no nursing experience had recently been placed in charge of the convicted hospital at Holloway over the heads of five trained nurses; whether this appointment was made on the advice of the Voluntary Advisory Nursing Board; and who were the ladies and gentleman who constituted that board.—Mr. SHORTT replied: It is not the case that a wardress with no nursing experience has been placed in charge of the convicted hospital at Holloway. The officer selected has had much nursing experience as she had been engaged on hospital duties for 17 years, and was selected to be a hospital officer in 1913, since when she has been wholly employed on hospital work. She is reported by the medical officers to be fully qualified and very capable. The Voluntary Nursing Board was not consulted as to the appointment, nor have they made any representation on the matter. It consists of the Medical Commissioner (Chairman); Dame Sarah Swift; Miss Hogg, Matron of Guy's Hospital; Miss McIntosh, Matron of St. Bartholomew's Hospital; Jessie, Lady Camoys; Dr. Mary Scharlieb; Miss Edith Blunt; The Governor of Holloway Prison; and the Hospital Lady Superintendent of Holloway Prison.

Insurance Act Medical Records.

Sir J. D. REES asked the Minister of Health whether the decision that doctors under the National Insurance Act should keep elaborate records of the cases of their patients had been cancelled; and, if not, whether that decision would now be cancelled in view of the cost of maintaining such records and of the objection generally entertained to bureaucratic registration, and even possible disclosure of incidents in the private life of patients concerned.—Sir A. MOND replied: The keeping of records was one of the original conditions of the insurance medical service. The present system was recommended in 1920 by a special committee, mainly consisting of medical men, among whom insurance practitioners were strongly represented. The initial cost has already been met, and the cost of maintenance is small. Resolutions were passed only last week in favour of the keeping of records by the annual conferences of panel committees and insurance committees respectively. In these circumstances I see no reason for reversing the decision that records should be kept.

Regional Medical Officers.

Mr. SUGDEN asked the Minister of Health what the cost had been in salaries, also expenses for travelling, of the officers and insured persons concerned, rent of premises, clerical assistance, &c., of the regional medical officers appointed by the Ministry of Health Act, 1920.—Sir A. MOND replied: The answer to the question is as follows: Salaries, full-time medical officers, £11,918 6s. 3d.; fees to part-time officers, £58 16s. Travelling expenses, officers and clerks, £1572 13s. 5d.; insured persons, £948 12s. 5d. Rent, offices, £2001. Part-time examination centres and women attendants, £2202 0s. 4d. Clerical assistance, &c., £7680 Incidental expenses (equipment, &c.), £810 18s. 6d. Total, £30,908 15s. 11d.

Mr. SUGDEN asked the Minister of Health how many cases examined had been referred to the regional medical officers by the panel doctors of insured persons concerned for assistance in treatment by consultation, and how many by the Friendly or Approved Societies and doctors for the purpose of deciding as to the fitness of the patient to return to work.—Sir A. MOND replied: The provision at present made in regard to the duties of the regional medical staff does not include the routine examination of cases of the kind referred to in the first part of the question. I would remind my hon. friend that Approved Societies and doctors were notified at the commencement of the service in November, 1920, that for an experimental period incapacity references only would be accepted. In reply to the second part of the question the aggregate number of references from Approved Societies, doctors, and insurance committees on questions of doubt as to incapacity for work for the period Nov. 1st, 1920, to Oct. 1st, 1921, was 50,318.

Women Visitors of Lunatic Asylums.

Viscount WOLMER asked the Secretary for the Home Department whether there were any women visitors of

THE LIFE OF THE HOUSE-FLY IN WINTER.

In the July number of the *Japan Medical World*, Dr. Harujiro Kobayashi, Sc.D., of the Chosen Government Hospital, Seoul, Korea, describes an investigation into the problem of the wintering of *Musca domestica*. Various claims have been made by writers on the subject to the effect that the fly passes the winter only in the adult stage, or only in the larval or pupal stage; but Dr. Kobayashi points out that the finding of any form does not necessarily imply wintering, since places have been noted where flies breed even in mid-winter. As a result of laboratory experiments and observation under natural conditions, Dr. Kobayashi has arrived at the following conclusions: (1) Certain species of *Musca domestica*, principally the female, "overwinter" in the adult stage in Korea. These flies are not in a state of hibernation, as active movement and oviposition occur from time to time. (2) In Seoul there are probably certain places where continual breeding of flies occurs in the winter. (3) No exact confirmation of the "overwintering" of larvæ and pupæ of the house-fly in Seoul has been obtained. (4) By experiments in feeding of the adult house-fly its longevity seems to be above 120 days in the winter. (5) *Scatophaga stercolaria* and *Calliphora lata* may also live through the winter in the adult stage. (6) *Stomoxys calcitrans*, *Sarcophaga carnaria*, and several other types apparently winter in the pupal or larval stages. (7) The destruction of wintering adults and detection of breeding-places in the winter must effectively counter the prevalence of the house-fly in the hot season.

COLONIAL HEALTH REPORTS.

East Africa Protectorate.—A belated report for 1918-19 contains some interesting passages relating to the public health. The general health of all sections of the community during the year was exceptionally bad. There was a considerable addition to the number of cases treated, which, even allowing for the normal rise in attendance at hospitals consequent on the development of the country, was much above the average. The mortality was abnormal, due to a variety of explainable causes which could not be controlled. The effect of the year's work was further reflected in the increase of the invaliding rate amongst the official class. Stoppage of leave, the withdrawal of every available man either from his billet here or who might have been selected to fill that post from home, resulted in the retention of an understaffed, overtaxed body of war-stale Government servants to carry on the administration of the country. Briefly the adverse conditions were the universal drought throughout the greater part of the year, due to the failure of both rains, and the consequent famine conditions, which greatly stimulated the continued existence of the usual communicable diseases. It became apparent that the return of large numbers of discharged soldiers and Carrier Corps porters had, and is having, its inevitable effect on the country; this, in spite of the most admirable efforts of the medical staff of the Carrier Corps. It was not possible for the civil department to take over the segregation of disease "carriers." Thus it was that various diseases became especially prevalent. The rapid spread of tuberculosis is becoming a serious menace. Equally with the rest of the world, this Protectorate was devastated by influenza, which swept like a tidal wave to its very confines, practically exhausting itself after nine weeks. Generally speaking, the most noticeable thing about it was that its virulence was more deadly in the colder up-country regions than in the moister and hotter coast areas. One condition which the progress of medical work during the war has demonstrated very clearly is the enormous liability of the African to helminthic affections. Fully three-quarters of the native population is infected, and the question of ankylostomiasis alone must have a marked bearing on the labour market. In fact, it is possible that the African lethargy inherent in this tropical region is largely dependent on this cause. In the principal towns trained anti-malarial gangs are employed clearing drains, filling in excavations, and oiling water. Rat-trapping and systematic investigation have been continued, though the coast and Nairobi were free from plague, and only one case was reported from Kisumu and eight at Nakuru. Voluntary prophylactic inoculations have been popular among Asiatic communities. A satisfactory vaccine has not yet been prepared that affords complete immunity from small-pox. The experience gained is that no strain, whether from overseas or locally prepared, has been successful over a prolonged period unless it has been reinforced. Generally a new strain has been substituted for the old. The total population is estimated at 2,627,080, composed of 5570 Europeans, 15,407 Indians, 202 Goans, 7468 Arabs, 236 other races, and 2,596,370 natives. Of the European male adult population (2193) 508 were classified as Government officials, 1105 as planters and farmers, 498 as commercial, 123 as missionaries, and 57 as professional men, the remaining 22 ing unclassified.

EVACUATION OF WOUNDED IN LAPLAND SNOW.

In his thesis for the degree of M.D.Vict., Dr. A. H. Macklin, who is now on his way as surgeon in the *Quest* to the Antarctic again, gives a good account, with excellent pictures, of the difficult country in Lapland about Murmansk, in which he was fighting in the North Russian *Syren* Expeditionary Force in 1918–19. The country was within the Arctic Circle, and very cold, though not always very cold as the Gulf Stream just touches the Murman coast. Major (as he then was) Macklin had to organise the evacuation of the wounded and sick from the mobile columns, and would seem to have done it well. The wounded man was carried out of action probably in a man-drawn sledge, but men could not carry him far, so the orderlies quickly changed him into another sledge drawn by reindeer or ponies, after they had dressed his wound and wrapped him in a special bag against the cold, and thus he went to the regimental aid-post. Here he was given food, had his wounds dressed and splints applied, had his feet dry rubbed and anti-frostbite socks put on. Then, his feet packed in dry hay if available, he was rolled up in his special bag again with a hot-water bag, and sent on. The "special bag" was a wadded quilt, 7 ft. by 7 ft., of wool and cotton in a close-woven cloth cover (*not* waterproof); this was secured round him, the foot-end turned up to prevent draughts, and a blanket tucked round his shoulders as well. He was then laid amongst hay in a sledge with a hood over him. At relay posts the animals might be changed, the patients got hot food, urinals, bed-pans, and were held for resuscitation if necessary, and in time they reached the advanced dressing station. The great problem was to avoid cold and frost-bite. Dr. Macklin, whose two years' experience as a dog-driver with Shackleton in the Antarctic, as well as his service in the war in the Italian Alps, give his opinion weight, recommends against frost-bite of feet: 1. No oil or grease. 2. Dry rubbing of feet, three pairs of socks, each successive pair a size larger than the last, and then loose boots; no constriction; two loose pairs of socks being better than three that are tight. Conditions were very different in North Russia from those in the other theatres of war. It sounds odd to find 20 reindeer in the war establishment of a medical unit ("10 to draw, 10 to break trail"). In that country, too, matches were very valuable; so while the "establishment" shows "Rations, 425 lb.," there also appears "Matches, 17 boxes."

Dr. A. H. Macklin is the son of Dr. T. T. Macklin, of Lancaster.

A GARDENING DIARY.

The medical man who devotes his scanty leisure to gardening or to the superintendence of the care of a garden will find in the Garden Lover's Diary, 1922, published by the Cable Printing and Publishing Co., at 2*s*., brief hints as to appropriate tasks for any season, interspersed with pleasant illustrations and a few verses.

K. V. C.—The address of the Medical Defence Union is 4, Trafalgar-square, London, W.C. 2.

We are asked to state that the old-established businesses of Messrs. John Bell and Croyden, Ltd., of Wigmore-street, London, W., and Messrs. Arnold and Sons, of Giltspur-street, London, E.C., have been amalgamated under one directorate.

We are informed that Messrs. Grout and Co., Ltd., of Great Yarmouth, having acquired the business of the Norwich Crape Company (1856), Ltd., will continue to manufacture the Norvic Crêpe Bandages.

Capt. W. C. Gunn to be Maj., and to commd. 5th (Scottish) San. Co.

Capt. H. N. Goode to be Maj., and to commd. 6th (Northern) San. Co.

Maj. J. D. Hart (late R.A.M.C.) to be Capt., and relinquishes the rank of Maj.

Lt.-Col. E. G. Peck, having attained the age limit, is retired, and retains the rank of Lt.-Col., with permission to wear the prescribed uniform.

Maj. W. A. Taylor, having attained the age limit, is retired, and retains the rank of Maj., with permission to wear the prescribed uniform.

Capts. F. Rowland, J. Anderson, J. McGlashan, and C. C. Grummitt, having attained the age limit, are retired, and retain the rank of Capt.

Supernumerary for Service with O.T.C.—Capt. E. W. A. Walker, having attained the age limit, is retired, and retains the rank of Capt.

TERRITORIAL ARMY RESERVE.

Col. R. Jackson, having attained the age limit, is retired, and retains the rank of Col., with permission to wear the prescribed uniform.

Capt. A. J. Williamson, from Genl. List, to be Lt.-Col.

Capt. S. S. Greaves, from Genl. List, to be Maj.

Capt. S. G. Reed, from 2nd Lond. San. Co., to be Capt.

ROYAL AIR FORCE.

Medical Branch.—Flight-Lt. A. Parker relinquishes his temporary commn. on ceasing to be employed, and is permitted to retain the rank of Capt.

Flight-Lt. (Hon. Squadron Leader) J. Keenan relinquishes his temporary commn. on ceasing to be employed, and is granted the rank of Maj.

Dental Branch.—The undermentioned Flight-Lts. are transferred to the Army Dental Corps (and will receive all emoluments from Army funds), with effect from the dates indicated. They will continue to hold their temporary R.A.F. commns. while attached to the R.A.F.: Actg. Squadron Leader C. L. Colbran and D. Blair.

INDIA AND THE INDIAN MEDICAL SERVICE.

Majs. A. E. J. Lister, T. S. B. Williams (Bt. Lt.-Col.), S. H. L. Abbott (actg. Lt.-Col.), J. E. Clements, H. B. Steen, E. Bisset, A. W. Overbeck-Wright, J. W. McCoy, R. M. Carter (Bt. Lt.-Col.), T. G. F. Paterson (Bt. Lt.-Col.), D. G. R. S. Baker, J. R. J. Tyrrell, Dewan Ganpat Rai, R. M. Barron (Bt. Lt.-Col.), W. R. J. Scroggie, T. H. Gloster, and H. H. G. Knapp to be Lt.-Cols.

Lt.-Col. L. J. M. Deas, on return from leave, has been posted as Agency Surgeon, Kotah. Maj. A. D. White has been permanently posted to Education Department, Bengal. Maj. J. E. Clements, on return from leave, has assumed the appointment of Medical Superintendent, Central Jail, Agra. Maj. J. H. Murray, C.I.E., has handed over the appointment of superintendent, Central Jail, Lahore. Maj. H. W. Acton has been posted to School of Tropical Medicine and Hygiene, Calcutta. Maj. H. H. King has been granted a year's leave. Maj. A. F. Hamilton has been appointed Professor of Midwifery, Grant Medical College, Bombay, and Physician, Bai Motlibai and Peti. Hospitals, vice Lt.-Col. S. C. Evans retired. Maj. D. P. Goil has been transferred from Murshedabad to Rajshahi. Maj. S. C. Chakrabatty, superintendent Central Lunatic Asylum, Berhampore, acts as Civil Surgeon, Murshedabad, in addition to his other duties. Maj. H. Watts, officiating civil surgeon, Sangor, has been appointed to executive and medical charge of Sangor District Jail. Maj. L. B. Scott, civil surgeon, Shillong, has been granted a year's leave.

METEOROLOGICAL CONDITIONS AND DISEASE.—A general meeting of the Association of Economic Biologists will be held on Friday, Nov. 11th, at 2.30 P.M., in the Botanical Lecture Theatre of the Imperial College of Science, South Kensington, London, S.W., when Dr. E. J. Butler, director of the Imperial Bureau of Mycology, will open a discussion on Meteorological Conditions and Disease.

NORTH ORMESBY HOSPITAL.—A new X ray department was opened recently at the North Ormesby Hospital, Middlesbrough, by Mr. J. H. Amos, manager of the Tees Conservancy Board, who raised practically the whole cost of the installation—namely, £1200. Acknowledging a vote of thanks, Mr. Amos stated that the hospital's annual income of about £17,000 came for the most part from the employers of labour and the working men in the area. Unlike most institutions of the kind, they were free from financial worries. The hospital was a household word in the district for homely comfort.

MEETINGS OF SECTIONS.

Tuesday, Nov. 8th.

THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.
Presidential Address by Dr. W. Langdon Brown: The Threshold of the Kidney. (*Discussion is invited.*)

PSYCHIATRY: at 8.30 P.M.
Paper:—Sir Frederick Mott: Further Researches upon the Reproductive Organs in Dementia Præcox.

Wednesday, Nov. 9th.

SURGERY: SUB-SECTION OF PROCTOLOGY: at 5.30 P.M.
The President will raise for informal discussion some topics of interest to the Sub-Section.
Cases also will be shown.

Thursday, Nov. 10th.

NEUROLOGY: at 8.30 P.M.
Discussion:—The Treatment of Persistent Pain due to Lesions of the Central and Peripheral Nervous System (introduced by Sir William Thorburn and Dr. Wilfred Harris).

SURGERY: Members of the Surgical Section are invited to join in the above discussion.

Friday, Nov. 11th.

CLINICAL: at *5.30 P.M. (Cases at 5 P.M.).*
Exhibition of Cases.

OPHTHALMOLOGY: at 8.30 P.M.
Papers:—Dr. W. S. Inman: The Relationship of Squint, Lefthandedness, and Stammering.
Dr. Charles F. *Harford: The New Psychology* and its Relation to Problems of Vision.

HARVEIAN SOCIETY OF LONDON, Town Hall, Paddington Green, Harrow-road, W.
THURSDAY, Nov. 10th.—8.30 P.M. Paper:—Dr. G. A. H. Barton: Ether: Some Simple Methods and Musings.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.
WEDNESDAY, Nov. 9th.—8 P.M., Mr. D. R. Wilson, Secretary of the Industrial Fatigue Research Board: The Work of the Industrial *Fatigue Research Board* and its Applications to Industry.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
Museum Demonstrations in the Theatre of the College for Advanced Students and Medical Practitioners:—
MONDAY, Nov. 7th.—5 P.M., Prof. S. G. Shattock: Cysts.
FRIDAY.—5 P.M., Sir Arthur Keith: Recently added Specimens of Clinical and Anatomical Interest.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.
TUESDAY, Nov. 8th and THURSDAY.—5 P.M., Fitz-Patrick Lectures:—Dr. R. O. Moon: Hippocrates in Relation to the Philosophy of his Time.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, Nov. 7th.—2.30 P.M., Dr. Arthur Saunders: Demonstration of *Cases* in Medical Wards. 5 P.M., Dr. Donald Armour: Practical Surgery (Lecture III.).
TUESDAY.—10 A.M., Mr. Steadman: Dental Department. 5 P.M., Mr. Banks Davis: Nasal Deafness. Lecture.
WEDNESDAY.—2 P.M., Dr. Burnford: Visit to Medical Wards. 5 P.M., Mr. Simmonds: Surgical Emergencies (Lecture II.).
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 5 P.M., Mr. Donald Armour: Practical Surgery (Lecture IV.).
FRIDAY.—11 A.M., Dr. McDougal: Electrical Department. 5 P.M., Mr. MacDonald: Cystitis. Lecture.
SATURDAY.—10 A.M., Dr. Arthur Saunders: Medical *Diseases of Children.* 2 P.M., *Dr. Owen:* Medical Out-patients.
Daily:—10 A.M., Visit of Post-Graduates to Wards. 2 P.M., In-patient, Out-patient Clinics and Operations.

or to cases of *dysuria* in which, again, instrumental examination reveals no renal or vesical origin. The importance of taking a wide view of all these cases as they present themselves becomes more and more apparent with the growth of knowledge. As I am this evening dealing with the urinary tract and not with renal conditions—though the distinction is frankly a loose one—I shall not enter into the question of mobile kidney and its obvious interest for both physician and surgeon.

INFECTION.

But it is, after all, the large and important subject of infection which provides the chief meeting-ground for physicians and surgeons in urinary diseases, whether the infection be of the urinary tract, of the kidney, or of the peri-renal tissues. I suppose the fact that so-called primary infections of the urinary tract are still very largely dealt with by surgeons is a survival of the old doctrine which taught that all infections were "ascending" in nature. Practitioners are still to be met who visualise a stone in the bladder, or some other gross lesion, so soon as a case of acute urinary infection presents itself. It is perhaps only fair to suggest that another reason why surgeons still hold a lien over many of these cases is that they have been more in the van of progress than have the physicians in the matter of elucidation of the problems connected with this subject. All the same, I am quite sure that it is in the interest of patients generally—I do not speak of any individual patient, nor of any individual practitioner—that the chief centre of interest in these cases should shift to the medical side. I say this quite apart from the fact that the general majority of these acute cases do very well with medical treatment. I say it because there are so many associated ætiological factors of a general kind, requiring careful consideration, in order to arrive at a complete diagnosis and a convincing programme of treatment. The state of the bowel, the nervous and vascular tone, the patient's habits—all these need investigation, because they have important bearings upon treatment during the actual attack, and even more important bearings upon prophylaxis against future relapses. This is not to say that the surgeon is incapable of taking long views, nor of giving excellent advice on all the points just mentioned, any more than it is to say that the physician is possessed of no technical ability. It is rather that this class of case is better adapted to the physician's routine methods of work than to that of the surgeon.

It is generally agreed that instrumental investigation is not only unnecessary but contra-indicated in acute urinary infections, except those of the urethra in gonorrhœa. And the more acute the infection the more emphatic the contra-indication. But from a lack of appreciation of the true pathology of these acute primary infections, this rule is by no means always followed. If, however, an acute infection persists, *despite adequate treatment* (and the opinion of someone fully versed in the particular problem may well be that the treatment has *not* been adequate) it is considered sound practice to use the cystoscope, and by its means determine more accurately the local conditions. There may then arise the question as to the desirability or otherwise of lavage of the pelvis of the kidney. Into this question I will not go fully this evening. I have an open mind in regard to this as, I hope, in regard to most other conditions in which we have alternative treatments, but I have not yet met with a case in which really careful and detailed management on general lines failed to cure, and in which pelvic lavage did. Let me repeat: "really careful and detailed management." And without going into particulars I may instance the dietetic part of the régime, which I find personally to be of the greatest importance, yet which is frequently quite neglected. In acute cases it too often happens that the firmly established British conviction that milk is the proper diet for all acute illnesses determines the matter here also. And even after the acute stage is over milk is often a staple article in the diet. My own experience leads me to exclude milk (as such) entirely from the diet in all these cases, and at whatever stage. In the cases of the disease occurring in nervous little girls, the suggestion to exclude milk from the diet is often met with great distrust by the mother, who fears loss of weight, and if this happens during the first week or so the milk is often promptly resumed. If time allowed I could refer to some very striking instances of emergence from prolonged acute attacks, and of rapid improvement in subacute and intermittent cases, as the direct result of changing the milk diet which the patients were taking for a diet free from milk, and also, I may add, free from eggs. I will only mention one case, that of an adult male who had been ill with an acute coliform infection for some six weeks, running a very high and intermitting temperature, and showing the usual depression, lethargy, foul tongue, constipation, and abdominal tympanites. After ordering a trial of antistreptococcus serum and silver injections intramuscularly, and getting no response in a couple of weeks, an eminent genito-urinary surgeon cut down upon both kidneys, freed them in the perirenal tissues, and stitched them in the horizontal position, explaining by the aid of diagrams that in this way the pelves would be able to drain more efficiently than was possible when the kidneys lay in the position chosen by Nature. The immediate result was complete anuria for three days, and a desperately ill patient. Then the former condition of affairs was gradually resumed, with the symptoms exactly as before, except that the abdominal distension was somewhat greater. This was the state of things when I saw the patient. From the naked eye and olfactory characters of the urine the infection was clearly coliform in nature. As a preliminary measure I changed the milk diet, expressing agreement with the rest of the treatment, and I promised to report concerning the urine, and whether or no I advised the use of a vaccine. Within three days, however, and before my report arrived, the patient had improved, and by the end of the week the temperature was normal.

We must not, of course, confuse the question, whether patients get well after pelvic lavage, with the question whether the lavage is necessary. Like many other organs in the body the kidney pelvis will tolerate chemical interference with little or no detriment, provided the technique be sufficiently skilled. No doubt each case must be treated on its merits—a principle, like a good many other principles, sufficiently hackneyed but too often disregarded. It is quite reasonable to make a local effort to reduce the pelvic infection in cases which continue to resist general measures of treatment. But I must confess that, in some of the cases that have come under my observation after the treatment has been adopted, the procedure has seemed to me to illustrate the triumph of technique over reason. I certainly think this is so where efforts have been made to soak the kidney with antiseptic, rather than to disinfect the pelvis. For if, as is allowed—nay, insisted—by one ardent apostle of this method, the kidney is really more sinned against than sinning in the matter of the infection, and if the microbe is not primarily but only indirectly responsible, by an upset in the "bacterial balance" (I borrow the expression for the moment) resulting from faults in the patient's general health—if things be so, then is it rational to think that an effort to get an antiseptic solution to percolate backwards through the kidney will materially alter the course of the disease?

The more I see of these cases of coliform infection the more convinced I am that until the function of the colon is healthy, the patient is not free from relapses or from a chronic bacilluria. And, since I saw, some years ago, a case of some 15 years' standing (if not longer) completely clear up after an emergency operation for intestinal obstruction caused by a band which had evidently caused some degree of mechanical difficulty for a very long time, I have given up any idea as to the possible duration of a bacilluria before

Notes, Short Comments, and Answers to Correspondents.

RAT WEEK, 1921.

IN connexion with the Rat Week fixed by the Ministry of Health for the week Oct. 31st to Nov. 5th a popular lecture on the Rat Problem was given on Oct. 28th at the Institute of Hygiene by Dr. C. W. Hutt, medical officer of health for Holborn. He explained that one object of the Ministry of Health in arranging the rat week was to endeavour to arrange that everybody should make concerted efforts to destroy rats and that rats should not be merely driven from one place to another. The only good point the rat has is that he preys on mice and keeps the number under. If we kill rats we must kill mice, otherwise the mice would find the struggle for existence less severe and multiply up to the extent of the food-supply. South Australia and Victoria recently suffered from a mouse plague which destroyed the wheat and hay, while horses fed on contaminated hay generally died.

Rats carry disease germs and spread disease to valuable domestic animals and man. Horse influenza is spread from stable to stable by rats. Where the outbreak of the disease has led to the closing of a stable the disease promptly appears in other stables in consequence of the migration of the rats as soon as their food-supply is stopped. Foot-and-mouth disease is carried by rats; pigs contract trichinosis by eating infected rats. At the Glasgow abattoirs it has been shown that 3 per cent. of the rats were suffering from trichinosis. More important still is probably the cause of meat poisoning, which is now known to be due to the pollution of raw and cooked meat with bacilli of the Gaertner group. The most dramatic of the hygienic dangers due to rats is the ever-present possibility of the spread of plague by their agency. Great as is the hygienic danger from rats the economic loss is even more appalling; it is estimated that at least £50,000,000 (fifty million pounds) worth of damage is caused every year in this country by rats alone. The damage done to the farmer is often equal to his rent and rates combined. The rat, like other rodents, must keep his incisor teeth from growing; to maintain them at the proper length he has to gnaw hard substances. He burrows under foundations, through walls, and by biting his way through joists at times causes the collapse of buildings. To free premises from rats the first matter to receive attention must be the prevention of the access of any more rats. Any defective house drain allowing an unobstructed passage from the sewer to the house must be remedied; all other possible entrances must be guarded by wire netting or metal guards. In the case of the black rat—a Blondin among rats—any means of access to the higher floors must also be blocked. This rat often gains access to the refreshment kitchens of city firms on the upper floor by running along telephone wires.

The cheapest way to destroy rats is by poison; the safest poisons to use are barium carbonate and liquid extract of squills; traps should be used after a poisoning campaign and in the winter, but they must be used with skill. The rat has the largest brain in proportion to its size of any mammal, and the trapper has to use all his ingenuity. The experience in Holborn is that the handling of a trap by a human being does not stop a rat from entering it. The Ministry of Health, Dr. Hutt concluded, should allow local authorities to spend a moderate sum on the purchase and free distribution of rat poisons, and as in the parallel instance of infectious diseases encourage the building up by public health committees of a more or less complete organisation to cope with this source of danger and loss to the community.

THE FOOD VALUE OF WHITE FLOUR.

WE have received from the hon. secretary of the Bread and Food Reform League some comments upon the official memorandum on Diet in Relation to Normal Nutrition, the subject of an annotation in last week's issue. The League would have liked to see more attention directed to the mineral content of oatmeal and whole wheatmeal. We alluded then, as on many previous occasions, to the danger arising from the milling of cereals. The energy requirements of the body vary from 2750 to 5500 calories per day according to the work of the individual. They are mainly satisfied by fat and carbohydrate in the proportion of 90 g. of fat to 530 g. of carbohydrate. Carbohydrate is chiefly consumed in the form of starch from white wheat flour in bread, cakes, pastry, &c.; the average quantity eaten per day may be reckoned as 2 lb. of bread, which furnish 2000 of the necessary calories. Proteins, salts, and vitamins are the other essential constituents of the diet. The protein and salt requirements are easily satisfied by the ordinary mixed food, but such food may not supply the vitamin requirement. Like proteins, definite amounts of each vitamin are required daily to keep the body in perfect health, but as yet the amounts have not been determined. The germ and outer portions of the cereal grains supply B-vitamin, the absence of which from the food leads to beri-beri, as has been clearly demonstrated both in the case of polished rice and white wheaten flour. Seeds of grains and legumes are the natural foods richest in B-vitamin. The milling processes remove the B-factor from the grain, and its loss is not easily made good by the other articles in the diet of the poorer classes. Flesh and fish are poor in respect of this vitamin, eggs are good, and so are most fruits and vegetables; yeast contains this vitamin in considerable amount. The addition of yeast to flour in the making of bread does not compensate for the vitamin lost in milling. No attempt is made to compensate for it in making cakes, &c., for which baking powder is used. Milk is variable in its vitamin content, and can hardly be considered as rich in B-factor. The loss of B-factor from the grain will only be replaced if eggs and large quantities of vegetables and fruits are eaten. As B-vitamin is a highly important constituent of the food, and is only amply supplied by the germ and outer parts of cereal grains, health is not promoted by the preference of the population for white flour. Whiteness does not represent goodness. The people should be encouraged to eat wholemeal flour, which can be obtained finely ground, so that they get a proper supply of B-vitamin. Highly milled flour is also deprived of good protein, A-vitamin, and salts. It is of special importance that patent cereal foods for infants should be prepared from the whole grain.

THE GLOVED HAND.

AN article in the September number of the *American Journal of Clinical Medicine* entitled "The Passing of the Rubber Glove," suggests that some American surgeons find that gloves render large incisions and multiple adhesions unavoidable, because of the marked diminution of tactile sensibility which they entail. In preference, preparation of the hands with Dakin's water-soluble chloramine soap is recommended, and a subsequent coating of varnish. It is difficult to appreciate the advantages of varnish over gloves, and multiple adhesions are more liable to follow button-hole incisions than a proper technical exposure. The crux of the matter remains—can hands be sterilised by washing? The evidence appears to show that while a temporary sterilisation may be possible the secretion of sweat glands soon floods the surface with cocci hidden in the ducts and other crypts in the skin. But the suggestion that the rubber glove is more trouble than it is worth may do good in stimulating glove manufacturers to produce a more durable brand.

THE COST OF CLEAN STREETS.

To keep Manchester "clean" involved last year an expenditure of £181,096, against an income of £109,247, while in 1914 the corresponding cost was £145,615—the increase being due chiefly to cost of labour and materials. The cleansing department of the city has a staff of 1056 employees, who have to look after 616½ miles of streets within the city. Over 1000 tons of refuse were disposed of every week-day, and the total amount exceeded 307,400 tons. Something like 2,108,000 tons of this refuse have been deposited on the Carrington and Chat Moss Estates—the property of the city—with the result that the moss land has been completely reclaimed; and owing to this and other factors the market value of this moss area has been greatly enhanced. There are now over 50 farmsteads on what was previously moss land, while the raw peat itself is used for bedding of horses and the manufacture of bacterised peat.

CONGENITAL HEART BLOCK.

AUTHENTIC instances of this condition being rare in medical literature, interest attaches to a unique case recently recorded by Drs. P. D. White, R. S. Eustis, and W. J. Kerr,[1] in which the irregular pulse was observed before birth and verified by the electrocardiograph on the fourth day after birth. The case was that of a Mongolian idiot whose fœtal heart rate was found to be markedly irregular. On the second day after birth the pulse showed variations between a regular rate of 80, a bigeminal rhythm of 105, a trigeminal rhythm of 120, and a rapid regular rate of 160. On the fourth day electrocardiograms showed partial heart block and evidence of right ventricular preponderance, succeeding examinations at two and half, five, and eight months suggesting that the partial heart block was paroxysmal. The anatomical defects were probably a patent ductus arteriosus with the usual interventricular septum defect The authors describe a second case of complete heart block in a child of 5¼ years, the congenital origin of which is strongly suggested by the age of the child and the absence of a history of severe diphtheritic infection. These two new cases are discussed in detail and correlated with the ten other cases found in the literature, in all but two of which the block was complete.

* Probably at least ¼ kidney tissue functioning.
† Probably less than ¼ kidney tissue functioning.

To my mind it is not at all extraordinary that Dr. Davies's patient died within one month of normal results for certain kidney function tests. The case is a good example of the danger of exaggeration of the usefulness of a single test. It is surely just as necessary in the case of the kidneys to weigh up all the evidence in estimating functional capacity as in the case of any other organ—e.g., the pancreas. Chemical tests provide most valuable additional means of estimating function—sometimes indispensable, often of little help—but no chemical pathologist claims that they do away in any sense with the necessity for complete clinical examinations of patients. Their great value lies in the fact that they enable a quantitative picture of the damage done to be made on the day of the test. With reference to the protein precipitated by acetic acid in the cold "lipoid-globulin" (Mackenzie Wallis) or "nucleoprotein," or whatever it may eventually be shown to be—no constant proportion between this protein and the total coagulable protein in any given sample of urine could be demonstrated in the three cases tested. (The urine of No. 4 was not tested for this protein.) The variations were from 0 per cent. to 100 per cent.

The Four Cases.

It was at the suggestion of Dr. G. F. Still that the urine was examined at frequent intervals (two-hourly by day and occasionally at night). The results of the examinations of Cases 2 and 4 are given in tabular form, with brief accounts of the four cases and a table of kidney function tests.

Brief Accounts of the Four Cases.

CASE 1.—E. C. Female. First admission. Jan. 31st, 1918, aged 7 years 11 months. "At intervals of about two months during the last two years the patient has complained of 'pain in the back' with passage of 'thick urine.' The backache may be accompanied by headache and very occasionally by vomiting. During such attacks the child takes no interest in anything, and her bowels are apt to be constipated, though she appears to require to micturate more frequently than is her wont. She has never complained of her eyes troubling her. No swelling has ever been observed by her mother.

"On examination throat normal, heart a little enlarged, its apex being one finger's breadth to left of nipple line in fifth intercostal space; a systolic murmur over the pulmonary area. Discs normal; urine with specific gravity of 1020, contains no sugar. Five early morning specimens obtained on separate days before rising contained no albumin. Shortly after rising, however, urine contains protein. Temperature normal." She was in the ward a little over a fortnight; on three occasions her evening temperature was recorded as 100° F.; otherwise nothing of note was observed until she developed diphtheria and was transferred to a fever hospital on Feb. 15th, 1918.

Second admission, Sept. 16th, 1919, age 9½ years. Her doctor found "albumin" in the urine and sent the case to hospital as "nephritis." "Every six or eight weeks the child suffers from attacks of listlessness with anorexia and slight vomiting after breakfast. Such illness generally lasts for two or three days and may be accompanied by 'bad nights,' the child lying awake till midnight. She never complains of headache but suffers from constipation. She does not have 'sore throats' and no swelling of any part of the body has been observed. She has been ailing thus for two or three years. At 1 year 3 months she was 'comatose' for two days. When 2 she caught chicken-pox, when 4 she suffered from whooping-cough, and when 5 from measles, and just before her eighth birthday she developed diphtheria, as already recorded under 'first admission.'

"The patient has one brother of 7½ who is healthy and has no albuminuria. Her father had influenza in January, 1919, followed by double 'pneumonia' and 'bronchitis.' After this attack albuminuria was reported. His urine had not been examined before this illness. There is no albumin now (see below). Her mother is healthy and has had no miscarriages; 13 years ago she had 'pleurisy.' No albuminuria has ever been found. There is no question of consanguinity, and no history of albuminuria in either the

TABLE II.—*Showing Results of Urinary Examinations.*

CASE 2.—Q. S., aged 19, female. Total days during which urine was examined at frequent intervals = 31, of which 7 are tabulated.

Meals.—Meals after 25/1/21 were given uniformly as on that day.

Tests for Nucleo-protein.—These were performed on 5/1/21 at 10 a.m. and 12 noon, when none was discovered; on 25/1/21 at 8 a.m., 10 a.m., and 12 noon, at each of which times 5 per cent. was discovered; on 2/2/21, at 10 a.m., 12 noon, and 2 p.m., when none was discovered.

Deposit.—The following were results of tests for deposits: 25/1/21, 8 a.m., pus cells 0, casts 0, oxalates 0; 4 p.m., pus cells 0, casts 0, oxalates 0.

Remarks.—25/1/21 and 29/1/21, albuminuria disappears and then reappears whilst erect. 30/1/21, cal. lact. gr. xxx. at 3 p.m., 8 p.m. 31/1/21, cal. lact. gr. xxx. at 8 a.m., 2 p.m., and 8 p.m. Cal. lact. gr. xxx. t.d.s. appears to make very little difference to the albuminuria. Note that if the urine had been examined on 31/1/21 at 10 a.m. or at 4 p.m. only, a cure might have been claimed—i.e., careful controls are essential. 1/2/21, 8 a.m., cal. lact. gr. xxx. At the end of the six doses of cal. lact. the albuminuria does stop temporarily. 2/2/21, there is an unusually *large amount of albumin* in the urine immediately after the cessation of treatment by cal. lact.

Presidential Address

ON THE

MEDICAL ASPECTS OF SOME URINARY DISEASES.

Delivered before the Section of Urology of the Royal Society of Medicine

BY SIR THOMAS HORDER, M.D. LOND.,
PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL.

MANY of the problems met with in uro-genital diseases are of joint medical and surgical interest, requiring the combined efforts of surgeons and physicians for their proper elucidation, and offering a field for both types of mind and for both kinds of training. The contemplation of the physician and the technique of the surgeon combine to secure the patient's welfare, for in the last analysis it is the study of the pathology of his disease and a survey of his general state which must dictate both diagnosis and treatment.

THE ENLARGED PROSTATE.

At first sight it would seem that the diagnosis and treatment of simple prostatic enlargement with its mechanical disabilities, to which our first president, the late Sir Peter Freyer, made such a valuable contribution, is a purely surgical affair; and no doubt in a large number of cases the medical interest in this condition is reduced to a minimum. And yet the mortality in prostatectomy, even to-day, is by no means a negligible affair. It is probably not less than 10 per cent. by the two-stage method, nor less than 15 per cent. by the one-stage method.[1] And this consideration alone raises the question of the desirability of reducing, if possible, the risks of operation. When the patient is elderly, as he frequently may be; when the urine is infected, as is not uncommon; or when the trouble coexists with some other known defect which may introduce its special risk during or after operation—then the case is no longer entirely surgical. Elderly patients are sometimes the subjects of latent diseases (only discovered by a complete overhauling), which may, or may not, constitute a bar to a major operation. Recently, during a routine examination of a candidate for prostatectomy, I found the patient to be a case of *chronic lymphatic leukæmia*. The reason he had been sent to me was that he was short of breath, and this symptom was thought to be of cardiac origin. Some treatment led to great improvement in his condition, and he stood his operation very well. I think most careful surgeons like their prostate patients examined methodically before the final decision is given relative to excision. I know this is not an invariable rule, because a short time ago I was asked to see a very ill man a week after his prostate had been removed, and whilst examining the bases of his lungs I came across a good-sized lump, densely hard and firmly fixed to one of his ribs—no doubt a metastatic deposit from a primary growth in the prostate, which I learned had been unusually difficult to remove. When my surgical colleagues ask me to see these candidates for prostatectomy, I find, after examination, that they can be placed in one or other of these three groups: (1) Cases in which examination reveals no abnormality which is not commensurate with the patient's age, or only reveals trivial defects which cannot be regarded as likely to prejudice the results of operation. (2) Cases in which one or more defects add to the normal risk of the procedure—defects in the heart, kidneys, blood-vessels, bronchial tract, lungs, portal system or central nervous system—but in which the degree of the defect does not contra-indicate major surgery, given very definite surgical indications for the procedure. In a good many cases some preliminary treatment will reasonably lower this added risk. (3) Cases in which one or more of these same disabilities is present to a degree sufficient seriously to imperil life by the operation, and in which little or no improvement is to be expected from treatment.

The exact surgical position is, of course, made clear to the physician at the time the patient is sent for examination, or during consultation. The surgeon may estimate that eventual difficulties are not likely to arise within a time shorter than the duration of life estimated by the physician; if so, and especially if the patient come into group 3, prostatectomy is definitely discountenanced. In group 2 come a good many cases demanding very careful judgment, as all who are familiar with this type of patient will know.

Mr. John Pardoe, a friend and former colleague of many of us here this evening, was speaking to me recently of the cases, very grave but fortunately uncommon, in which late hæmorrhage followed prostatectomy, and he confessed himself puzzled as to their meaning. An obvious suggestion is that the underlying cause is sepsis; but this is by no means certain, or demonstrated, and here seems one more problem in the elucidation of which physicians and surgeons are probably both concerned.

Whilst it is the patient's general state, rather than the local lesion, which has medical bearings in prostatic enlargement, it is both the general and the local condition which are of interest to the physician in

NEPHROLITHIASIS.

Indeed, the surgical interest in this disease centres round the end-result rather than round the pathological process. It is true that our metabolic studies do not, as yet, give us any very definite lead in the direction of the prevention of uratic and oxalic deposits in the kidney and renal pelvis; but, at least, the main principles of prevention are understood, and it is fairly certain that a large number of patients are kept in a safe position with regard to the re-formation of calculi when once they have been frightened into obedience by the experience of a nephrotomy or a nephrectomy. One of the most interesting problems that presents itself is the type of case in which calculi are known to be present in the kidney, perhaps in both kidneys, but the condition is largely latent as regards pain or hæmaturia. In these cases it is important to assess, as nearly as may be, the probable future history of the patient in respect of his trouble. His renal adequacy, and the question of sub-infection of the urinary tract—perhaps of the intermitting kind—are points which need investigation, and must be taken into account, together with points of general health and future mode of life, before a sound opinion can be given as to whether any surgical procedure shall be adopted and what its nature shall be.

PHOSPHATURIA AND OXALURIA.

Phosphaturia and oxaluria are probably of more medical than surgical interest, when not complicated by concretions of a gross kind. The known associations of both of these conditions with gastric and intestinal dyspepsia, and the close association of phosphaturia with nerve states, make it of paramount importance that the patients suffering from them should be fully and carefully examined. In the great majority of the cases it is found that such symptoms as are referable to the urinary tract are of secondary and not of primary origin, and that they yield to treatment on general medical lines, if this is carried out thoroughly and perseveringly. Again and again, however, this class of case requires, for its satisfactory elucidation, that both surgical and medical aspects of the problem be passed in review.

I will not stay to refer to difficult cases of *renal pain* with no obvious cause discoverable by the surgeon, and the moot question of exploration that arises in connexion with them; to cases of obscure *hæmaturia*,

---

[1] Since writing this Mr. Thomson Walker informs me that statistics at St. Peter's Hospital show a smaller total mortality than this: 8·13 per cent. in 1276 cases from 1901 to 1918.

On examination the patient is tall, thin, and "weedy"; pale complexion; nothing abnormal found in any of the systems. Blood pressure is 122/85; temperature is 99° F., nearly every evening. The albuminuria is postural in type, but protein reappears while recumbent (see urinary tables).

TABLE IV.—*Results of Kidney Function Tests.*

Test.	Normal findings.	Cases.			
		1	2	3	4
Urea conc. (MacLean and de Wesselow). $\frac{\text{Urea }\%}{\text{Urine c.cm.}}$ at end of—					
1st hour ..	—	$\frac{0{\cdot}81\ \%}{240\text{ c.cm.}}$	$\frac{2{\cdot}84\ \%}{6\text{ c.cm.}}$	$\frac{3{\cdot}64\ \%}{60\text{ c.cm.}}$	$\frac{3{\cdot}32\ \%}{120\text{ c.cm.}}$
2nd hour ..	2 to 4 %	$\frac{2{\cdot}59\ \%}{120\text{ c.cm.}}$	$\frac{3{\cdot}53\ \%}{105\text{ c.cm.}}$	$\frac{3{\cdot}78\ \%}{60\text{ c.cm.}}$	$\frac{3{\cdot}44\ \%}{70\text{ c.cm.}}$
3rd hour ..	—	—	$\frac{3{\cdot}58\ \%}{48\text{ c.cm.}}$	$\frac{3{\cdot}10\ \%}{60\text{ c.cm.}}$	—

* Excluding the urinary system.
† Gr. viiss. t.d.s. for 7 days. ‡ Gr. xxx. t.d.s. for 2 days.
N., normal. F. low, fairly low. Ent., enterococcus.
E., evening. Neg., negative.

Centrifugalised deposit contains a very small number of hyaline casts, epithelial cells, white and red blood corpuscles; always a trace of mucus. No oxalate crystals ever observed. Culture of urine sterile. Total volume of urine per 24 hours is normal.

Conclusions.

1. "True proteinuria" probably never reappears in the recumbent position in cases of cyclic proteinuria. If proteinuria does recur while the patient is lying in bed an organic lesion should at once be suspected. "True proteinuria" is emphasised because it is obviously necessary to make certain that the protein does not come from other parts—e.g., the vagina.

2. Posture appears to be an important factor in causation but not the only factor, because in three cases on certain days protein disappeared from the urine while still in the upright position.

3. Cases 1 and 2 are regarded as true cyclic proteinurics. Case 3 is regarded as organic for the following reasons: (*a*) Proteinuria occurred while recumbent on several occasions; (*b*) a few granular casts and a few degenerate pus cells were found more than once; (*c*) the boy had an evening temperature of 99° to 100°F., and a leucocytosis of 21,600 for which no cause was found unless it was kidney disease. Culture of the urine yielded an enterococcus on one occasion (but was sterile at a later date); (*d*) occasionally the boy passed large amounts of protein—e.g., 0·33 per cent. (Aufrecht). Case 4 is also regarded as organic because of pyuria, the fact that protein recurred while recumbent and occasionally was large in amount, and the evening temperature of 99°F.

4. The albuminuria of a small organic kidney lesion may be postural in type, or in other words, the amount of protein may fluctuate in organic albuminuria so as to simulate a condition of functional cyclic albuminuria. In the latter condition, however, once the protein has disappeared from the urine as a result of lying down, it probably never reappears while the ordinary recumbent position in bed is maintained.

5. It is possible that in certain cases of mild organic disease of the kidney (or other part of the urinary tract) the proteinuria is postural in type simply owing to the drainage of the foci of disease in the erect attitude.

6. The fact that in postural proteinuria the "albumin" may appear, then disappear, and then reappear (the erect posture being maintained throughout) should make us very chary of claiming cures as a result of any particular treatment (e.g., by cal. lact.). Careful controls are essential.

I desire to express my thanks to Dr. G. F. Still, Dr. H. W. Wiltshire, Mr. J. W. Thomson Walker, and Dr. A. C. D. Firth for the opportunity to investigate these cases.

THE ESSENTIAL CAUSES OF ADENOIDS AND THEIR ASSOCIATION WITH RICKETS.

BY H. MERRALL, M.B., CH.B. VICT.

IT is obvious to even a desultory reader of contemporary medical journals that many conflicting opinions, and some downright ignorance, exist on the subject of that hyperplasia of the pharyngeal tonsil known as adenoid vegetations. Concerning the ætiology of this extremely common condition the writings even of deservedly acknowledged experts are vague and unconvincing, while their opinions on the proper treatment of the secondary enlargement of the palatine tonsils are flatly contradictory. Communications have been read at important medical gatherings preaching the rank heresy that operative treatment is unnecessary; and in widely read daily papers the public is periodically misinformed on the subject of this, perhaps the commonest, and in its national aspect perhaps the most important, disease of our time. The exacting work of the general practitioner may sufficiently excuse his lack of knowledge, and the significance of the immense accumulation of expert observations is largely misinterpreted or overlooked.

In this paper I shall endeavour to show: (1) the essential cause of "adenoids"; (2) that the close association between adenoids and rickets, long ago pointed it should be regarded as incurable. In a chronic case, whether in child or adult, no point in treatment having the least bearing upon the bowel condition seems too trivial for attention. The choice of aperients is an important point, and patients should be made to understand that it is not the frequency or regularity of the bowel action that matters so much as the character of the stool passed.

CONCLUSION.

It is, however, my métier to-night not to deal specifically with treatment of any type of case, but rather to indicate the importance of taking broad views of the pathology underlying several types. Upon staphylococcus infection I will not dwell, but merely remind you of the great importance of the cases, because of their frequent obscurity and also because of their great gravity. Both the urinary infection and the peri-renal abscess that may develop are manifestations of a pyæmia, and although prompt surgical measures are of the utmost value in draining foci when these are established, the main onus of treatment is medical in coping with the underlying septicæmia.

Before leaving this important matter of urinary infection, the mere knowledge of the fact that no longer can we regard the mere discovery of micro-organisms in the urine of a patient as indicating an infection within the urinary tract is sufficient to establish the thesis that all cases should be considered to have possible medical bearings until this is proved not to be the case. For what is the actual position? Micro-organisms in the urine may indicate one of the following conditions: (1) A mere elimination of these from the blood stream without any urinary infection at all; (2) a focal infection at some point in the urinary tract; (3) a focal infection outside the urinary tract, but communicating with it either by gross continuity or by lymphatic spread; (4) a diffuse infection of the urinary tract; (5) that the urinary tract is a "carrier" of the micro-organism, as seems the nature of some cases of bacilluria. With all these possibilities before us it is, as I say, clear that wide views should be taken of any case with which we have to deal.

OBSERVATIONS ON POSTURAL PROTEINURIA.

BY G. A. HARRISON, B.A., M.B., B.CH. CANTAB.,
BIOCHEMIST, KING'S COLLEGE HOSPITAL, LONDON.

OWING to the interest which has recently been shown in "albuminuria of uncertain origin,"[1] the notes of four such cases are recorded below. If postural proteinuria be considered to include all cases of "albuminuria" which decreases or disappears on lying down only to increase or reappear on rising again, then the term includes at least two distinct groups of patients—viz., group (1) where no evidence is forthcoming of any organic lesion of the kidneys (or of any part of the urinary tract)—I propose to call this group "cyclic proteinuria" or "functional postural proteinuria"—and group (2) where there is evidence of some slight organic lesion of the kidneys (or of some part of the urinary tract)—e.g., slight pyuria, occasional casts (other than hyaline), &c.—I propose to call this group "organic postural proteinuria." Naturally, where the actual position of the lesion can be defined, the cases will be termed nephritis, pyelonephritis, pyelitis, cystitis, prostatitis, &c., even though the resulting proteinuria may be postural in type at some stage of the disease (for instance, occasionally in nephritis, during recovery, the albuminuria may become postural in character); I am not referring to such cases under the heading of organic postural proteinuria, but rather to those mild organic cases which cannot so be labelled.

Of the four cases I regard Nos. 1 and 2 as cyclic proteinuria (functional postural proteinuria) and Nos. 3 and 4 as organic postural proteinuria. It is more than likely that all such groupings are purely artificial. It is possible that it is merely a matter of the severity of the disease. Very mild organic lesions tend to recover of themselves and are apt not to be followed up. It may be that our methods of investigation are not sufficiently delicate to prove the existence of an organic lesion in cyclic proteinuria.

Importance of Careful Investigation.

From the point of view of examination for life insurance, there is a tendency to regard cases of cyclic proteinuria as healthy beings, whereas cases of organic postural proteinuria would probably be deferred or heavily loaded on account of the results of the microscopical examination of the deposit, if such examination was performed. The main purpose of this paper is to indicate the importance of very careful investigation of these cases of postural proteinuria, lest the patient belong to the second group (organic), and the early stages of disease be allowed to pass untreated. It is admitted that the majority of the second group probably recover spontaneously, but it is possible that some of them may advance, and so occasionally justify the suspicion with which postural proteinuria is viewed by insurance companies. It is suggested that the examination of the urine for protein at frequent intervals (e.g., every two hours for one or two days), combined with a microscopical examination of the centrifugalised deposit of some of the specimens in which protein is found, provides a simple (though somewhat laborious) method of determining whether the patient belongs to the group of organic postural proteinurics or to the group of cyclic proteinurics.

I consider the term "cyclic proteinuria" very appropriate for the latter group. It contains no suggestion of the underlying cause, but reminds one of the extraordinary variations which may occur in any given period of 24 hours—variations, which to my mind, it is essential to demonstrate before diagnosing cyclic proteinuria. "Albuminuria of adolescence"[2] is not sufficiently comprehensive because this condition may occur long before puberty; "hæmatogenous albuminuria" is far too comprehensive because many physicians use it to embrace albuminuria resulting from various anæmias, or occurring in the course of acute specific fevers, &c. "Proteinuria" is obviously a more accurate term than "albuminuria."

I wish particularly to emphasise a fact often overlooked in judging the value of quantitative renal function tests—viz., that it is estimated that probably not until about three-quarters of the total kidney tissue has functionally been put out of action do such tests reveal any abnormality. I refer, of course, to estimations of the functional activity of the two kidneys together. The surgeon is able with the aid of ureteric catheterisation to compare the function of the two kidneys. How far "catheter inhibition" may interfere with the absolute quantitative measure of the function of each kidney separately is at present imperfectly known. Obviously, therefore, in cyclic proteinuria the current tests of renal efficiency will chiefly be of negative value in that they exclude very gross kidney lesions. While discussing this point I should like to draw attention to the case published by Dr. Ivor T. Davies in THE LANCET of Dec. 18th, 1920. It is perfectly reasonable to consider that at the time the diastatic index was normal (a month before death) probably more than a quarter of the total kidney substance was functioning—that is all the result implied at the time the test was made. It is necessary to repeat kidney function tests at intervals if it is desired (*a*) to show that the amount of damage has not reached the "three-quarter line,"[3] or (*b*) the degree of damage having reached that point, to obtain

---

[1] THE LANCET, 1920, i., p. 868, and 1921, i., pp. 116, 126, and 136.

[2] Dr. R. Hingston Fox: THE LANCET, 1921, i., 116.

[3] Three-quarters is adopted merely as a rough working hypothesis.

At a meeting of the section of the Royal Society of Medicine devoted to the subject of "the causes and non-operative treatment of adenoids," to which reference has been made, many causes of adenoids were given by various speakers—e.g., faulty digestion of starch, bottle-feeding, improper food; all these are also claimed by pediatrists to cause rickets. It will doubtless be urged that defective feeding will produce rickets in animals, but Zeim's experiments showed that deformities in the neighbouring bones are induced in puppies by closing up their nostrils.

Essential Element of Causation.

The essential element in the causation of adenoid vegetations is the overworking of the lymphatic glands situated behind the soft palate by repeated colds and by the exanthemata.

In this situation exist a number of collections of adenoid or lymphoid tissue, called lymphatic glands, and when in certain places, tonsils. As Waldeyer pointed out, they form a double ring, inner and outer, the members of the latter ring being situated amongst the muscles of the neck and under the skin, and only becoming obvious when swollen, inflamed, or suppurating. The inner ring is formed by the pharyngeal tonsil, also called Luschka's gland) by the Eustachian tonsils (collections of lymphoid tissue situated at the orifice of the tubes of that name), by the palatine and lingual tonsils, and by various unnamed patches of adenoid tissue on the walls of the pharynx and naso-pharynx. The glands of this inner ring all possess two striking features common only to them and to certain similar structures in the alimentary canal —i.e., they appear on the surface, are subepithelial instead of being covered by superimposed structures, as are the lymphatic glands of the limbs and trunk; and they possess no afferent lymphatic vessels. Enlargement or catarrhal inflammation of the naso-pharyngeal tonsils constitutes adenoids. These tonsils are not dangerous vestigial relics, but extremely important organs constituting local defences, and bearing a large share in the production of "immunity." The subepithelial members are situated at various points in the alimentary canal in zones which have been referred to as vulnerable spots. The glands forming Peyer's patches, and even the appendix vermiformis, are examples of these defences. These glands are composed of nodules, the lymph follicles, consisting of a network of adenoid tissue in which are embedded large and small lymph cells identical with the leucocytes in the blood. Both varieties are powerfully phagocytic, but the smaller type is far more numerous; its members pass into the blood directly and also through the efferent lymph vessels, and constitute 20 per cent. of the total white blood cells.

The subepithelial masses of adenoid tissue lie so close to the surface that lymph cells and epithelial cells are intermingled. Though scarcely represented in fœtal life they reach their highest development and are functionally most active in the early years of childhood, when immunity is acquired against the exanthemata and other infectious diseases. The facts that lymphocytosis occurs most frequently during childhood and that lymphocytes form a relatively larger portion of the blood in very young children are thus explained. Numerous important investigations have been made with reference to the function of these glands by Watney, Ranshoff, Ruffer, Flemming, and Digby,[16] amongst others, and the phagocytic action of the lymph cells, which goes on freely not only in the interior of the glands but on the surface, must be regarded as conclusively proved.

Inflammatory enlargement of the subepithelial glands, with consequent lymphocytosis, is characteristic of a variety of diseases—e.g., tuberculosis, diphtheria, malaria, mumps, rickets, syphilis, the exanthemata, and recurring colds; in the last case the glands affected are the pharyngeal and palatine tonsils. Consisting of a congeries of lymphocytes, held together by a supporting meshwork of retiform tissue, these tonsils become greatly enlarged when the throat and nose are invaded by the micro-organisms which occasion a cold. The first to suffer is the pharyngeal tonsil; repeated attacks render the enlargement permanent. The tonsil becomes fibrous and its defensive functions are thereby lessened. A more severe cold results in the destruction of many of the lymphocytes, and these, with the increased amount of mucus secreted, constitute the muco-purulent discharge of catarrh. A great number of micro-organisms have the property of causing symptoms of a cold. R. W. Allen[17] has identified five, but it is highly probable that besides these, and those others which cause the various exanthemata, many more produce catarrh.

Functions of the Nose.

Leaving out of consideration the olfactory, respiratory, vocal, and gustatory functions, also the drainage of the sinuses and ventilation of the Eustachian tubes, the principal nasal functions are to filter, warm, and moisten the air. According to StClair Thomson and R. T. Hewlett,[24] from 1500 to 14,000 organisms enter the nose during one hour's tranquil respiration.

The cilia sweep back the grosser particles, and the nasal mucous membrane has been said to be bactericidal; the expired air is sterile, but this alteration, in virtue of some ingenious experiments performed by Greville Macdonald and others, have proved this sterility to be due to conditions obtaining in the nose and naso-pharynx. It is obviously quite impossible that in health all the micro-organisms entering the nose are expelled by the ciliated epithelium or entangled in its bactericidal mucus. Diagrams have been made to show how the air in its passage through the nose arches upwards, backwards, and downwards. But for each and every individual micro-organism to come into contact with one or other of the walls of the nasal cavities and for none to pass through the nose without touching these walls during the short period of the time taken in the performance of even only one respiratory act, is manifestly impossible. Entering through the nostrils, the air impinges on the posterior naso-pharyngeal wall in the situation of the pharyngeal tonsil and is deflected into the larynx. The remarkable researches of Metchnikoff, which proved the function of the white blood cells to be not merely scavenging but also effectively bactericidal, should have led us to suspect the fate of the hordes of micro-organisms entering the body during respiration. Is it not remarkable that the stream of air entering through the nose first impinges on a group of surface defences? The sterilisation of the air is partly, perhaps mainly, performed by the naso-pharyngeal tonsils which are the first to suffer from enlargement, inflammation, and suppuration, the other members of the inner ring only becoming affected secondarily.

Presence of Micro-organisms in the Subepithelial Lymphatic Glands.

Digby[18] found the presence of bacteria easily demonstrable in the vermiform appendix of the rabbit, and quoted Ruffer and Butterfield who, working independently, found them present in large numbers in human tonsils. Mucus from the tonsils of four healthy (human) subjects was found by Ruffer to contain numbers of "leucocytes full of microbes."

It is highly probable that the small lymphocytes passing between the epithelial cells attack, kill, and absorb the micro-organisms present on the surface, and return with them to the interior of the gland from which they emerged. They are definitely phagocytic and motile. They originate from the same blastodermic layer as the digestive tract. General increase of lymphatic structures, particularly of the subepithelial variety, signifies prolonged bacterial assaults. The heart may be weakened by the presence of toxins in the blood, and therein lies the explanation and the cause of status lymphaticus.†

The overworked, chronically enlarged pharyngeal and palatine tonsils become a source of danger to the individual and may give rise to toxæmia. "That chronically enlarged tonsils or marked adenoids have lost their defensive powers, and come to resemble a choked filter, is shown by the greater frequency with which adenoid children contract diphtheria and scarlatina and by the severity of throat and ear complications in such cases" (Thomson).[19] And besides the remarkably prompt and beneficial results following operative removal of adenoids, it is a matter of almost daily observation to note the improvement in the complexion and health of patients suffering from naso-pharyngeal catarrh after a course of local treatment. The frequency with which appendicular troubles are relieved by similar throat treatment cannot be explained as coincidence. Pybus[20] mentioned the occurrence of appendicitis following throat affections in 1915, and Eustace Smith points out that in some specific fevers—e.g., scarlatina—it is found post mortem that all the subepithelial lymphatic glands are affected.

Examination of the blood reveals, as the phagocytosis or lymphocytosis would lead one to suspect, a degree of anæmia. There is also diminution of alkalinity—sometimes referred to as acidosis—due probably to respiratory obstruction occasioning increased production of carbon dioxide. Some of the mental and physical defects noticed have been explained by these changes in the blood. Many authorities[21] have commented upon the improvement after operation. Given anæmia, lack of muscular tone is inevitable, and the habit

---

† Ehrlich suggested that preliminary to phagocytosis the blood plasma played a part in virtue of alexin and the amboceptor, and Wright teaches that micro-organisms are first acted upon by a mysterious opsonin which prepares the way for the phagocytes. But the phagocytic action of the large and small glandular lymphocytes appears difficult to explain by either of these theories.

TABLE III.—*Urinary Examinations.*

CASE 4.—S. G., aged 17, male. The urine of this patient was examined at short intervals for 1½ days only.

Remarks.—21/3/21 (3 a.m. and 6 a.m.): Albuminuria while recumbent. 22/3/21 (7 a.m. and 8 a.m.): Albuminuria recurs though lying flat.

maternal or the paternal grandparents. Specimens of urine have been obtained from father, mother, and brother, in the morning immediately before rising, at midday, and in the evening. No albumin had been found in any of these specimens.

"The child is pale with a waxy complexion; dark lines are visible under her eyes and she is apt to get 'styes.' No abnormal degree of lordosis is present. Her tongue is clean and both tonsils have been removed except for a fragment of tonsillar tissue on the right. Nothing abnormal in lungs or abdomen; apex of heart one finger's breadth to left of nipple line in fifth intercostal space, but heart sounds normal; fundi and discs quite normal; urine, acid to litmus has a specific gravity of 1025. Albumin, sugar, and acetone bodies all absent. The deposit shows nothing abnormal, no calcium oxalate crystals or casts. Albumin in evening specimen if the girl is allowed to get up during day; it never reappears while recumbent. On several occasions protein has disappeared and then reappeared whilst erect. The patient passes a normal quantity of urine during the 24 hours." She stayed in hospital until Oct. 7th, 1919, for the purpose of the observations here given. She vomited once during the evening, probably due to an indiscretion in diet. She developed a stye in her left upper eyelid on Oct. 1st, 1919. Otherwise she remained perfectly healthy throughout.

On March 21th she came to see me as an out-patient: "She has been up and about like other healthy children since leaving King's College Hospital on Oct. 7th, 1919, nearly six months ago. She has suffered two or three attacks of listlessness with anorexia, and there has been very occasional morning vomiting during these attacks (compare history obtained on second admission). Otherwise she has been perfectly well. She has been to school throughout. I have examined her thoroughly all over but find nothing fresh. Her abdomen has been carefully palpated both in the erect and the recumbent position for any sign of movable kidneys with negative result. The lower margin of the liver is just palpable."

In May, 1921, this patient developed miliary tuberculosis, culminating in death on June 28th. At autopsy the findings were typical of the condition. The lungs were so closely studded with miliary tubercles that on section no normal tissue was anywhere visible. The mediastinal glands were much enlarged and caseous, especially about the left bronchus. Both kidneys were slightly enlarged; cortex pale; capsule slightly adherent; surface of each nodular, due to cortical tubules. On section both showed very numerous tubercles, especially in the cortex; the left organ also contained a fair number in the medulla. Histologically a complete investigation has not yet been made, but it is doubtful whether anything of value re the postural proteinuria could be demonstrated with such extensive tuberculous changes superimposed. The cause of death is of special interest in that Mazzolini (*Ric. Osped.*, Jan. 15th, 1920) regards postural proteinuria as possible evidence of incipient tuberculosis.

CASE 2.—Q. S., age 19, female. "Admitted December, 1920, complaining of malaise and pain in the back for two years; has not been able to work since November, 1919, because she often feels faint. Has had to come out of church for the same reason; actually fainted twice, a year ago. Pain in back not relieved by lying down. She has never vomited. Vision subjectively is perfect; no swelling ever observed. She had measles and whooping-cough as a child, and scarlet fever at 12. Seven years ago she attended this hospital for 'spinal curvature' and believes that she also had a 'bad heart.' Both parents alive and well; no consanguinity. Three brothers and one sister alive and well. Mother's sister died at the age of 40 from 'kidney trouble.'

"On examination, patient's complexion pale, she looks frail and 'weedy,' and is somewhat thin. No glandular enlargement. Slight lordosis is present. Nothing abnormal detected in any of the systems. Kidneys not palpable in either erect or recumbent position. Systolic blood pressure, while recumbent, varies from 98 to 112 mm. Hg, and while upright from 92 to 116; after taking exercise it has risen to 136, falling to 112 in five minutes, temperature normal. Posture is perhaps the chief, though not the only, factor in the production of albuminuria (see urinary table). On one occasion she has stayed up all night and has gone to bed in the day. As would be expected she passed albumin that night, but not during the day, while in bed. Protein has never reappeared in the urine while the patient is recumbent. Calcium oxalate crystals are frequently found in the urinary deposit, but never any cells or casts. Cultures of the urine have not been made. The effect of calcium lactate is shown in the urinary table. The quantity of urine in the 24 hours is normal. She has felt faint and turned very pale several times while in hospital, and has had to lie down, but has never become unconscious. Menstruation normal; X ray of chest reveals nothing abnormal."

CASE 3.—A. K., age 15, male. "Admitted January, 1921, for investigation. Albumin has been found in the urine, and there is a history of two 'fits' (1) 18 months previously; (2) Christmas, 1920. The history is not typical of epileptic fits; more probably they were only faints. Otherwise the boy has been perfectly healthy; no shortness of breath, no swelling, 'vision perfect.' Had measles and chicken-pox as a little boy and German measles at 11; has never had scarlet fever or any sore throats. His father and mother alive and well; they are second cousins. He has one brother of 24 who is said to have albuminuria, and one sister of 21 who has fainted four times. Specimens of urine have been obtained from brother and sister in the morning before rising, at midday, and in the evening. The brother's midday specimen contains a very slight trace of protein, but nothing abnormal in centrifugalised deposit. The other specimens are protein-free, as are those obtained from the sister. Further investigation is not possible.

"On examination the boy looks perfectly healthy. Nothing abnormal has been discovered except for the evening temperature of 99° to 100° F., the leucocytosis, and the urinary findings. No lordosis; X ray chest normal. Kidneys not palpable erect or recumbent. Discs normal. No œdema. Testes and cords normal. White blood corpuscles 21,600, of which polymorphs = 76·4 per cent., eosinophils 1·2 per cent., lymphocytes 16·8 per cent., hyalines 5·2 per cent., and mast cells 0·4 per cent. Wassermann negative. Systolic blood pressure recumbent = 122, erect 96 to 122. The albuminuria is postural in type, but on several occasions protein has reappeared while the patient remained in bed. On two occasions the percentage of protein excreted has been high. At different times granular casts, hyaline casts, and leucocytes have been found in very small numbers; calcium oxalate crystals have never been seen; there is always a trace of mucus. Culture of urine on one occasion yielded an enterococcus, on second occasion sterile. Tubercle bacilli have not been found. Calcium lactate (gr. xxx. t.d.s. for six doses) has not controlled the albuminuria. The quantity of urine passed in the 24 hours is normal. The very marked variations in the quantities of protein passed on different days suggest that the albuminuria may have been postural in type simply as a result of the drainage of the foci of disease in the erect attitude."

The boy was readmitted in April, 1921, under Mr. Thomson Walker, who has very kindly allowed me to report the following findings: cystoscopy, nothing abnormal observed in the bladder or at the mouths of the ureters. X ray of kidneys: no evidence of calculus. Catheterisation of ureters; free flow of urine from each side; catheter passed more easily on the left than on the right. The urine from the right kidney contained a fair number of granular and a few hyaline casts; on the addition of a few drops of salicylsulphonic acid, the specimen went almost solid, indicating the presence of considerably more protein than could be accounted for by the small quantity of blood resulting from the passage of the catheter; culture sterile. No casts were found in the urine from the left kidney; there was a trace of protein due to the slight amount of blood resulting from the operation.

CASE 4.—S. G., aged 17, male. Admitted March 15th, 1921, for investigation. Albumin had been found in urine during a medical examination required when applying for an appointment. Family history and past history: *nil ad rem.*

Ziehl-Neelsen method for acid-fast bacilli; (2) each tonsil was cut into two halves with a sterile knife and films made from the cut surfaces. These films were examined for acid-fast bacilli in the usual way; (3) one half of each tonsil was fixed, dehydrated, and embedded in paraffin. Sections were stained by (*a*) hæmatoxylin and eosin for histological structure, and (*b*) carbol-fuchsin and methylene-blue for acid-fast bacilli; (4) the other halves of the two tonsils were ground together in a mortar (with a little sterile sand added to facilitate disintegration), digested with 40 c.cm. of 1 per cent. antiformin for an hour to destroy secondary organisms, centrifuged and washed several times, and the resultant deposit inoculated subcutaneously into guinea-pigs.

Results of Examination.

One hundred cases were investigated. Unfortunately in five instances the animal test was omitted, and in one instance the crypts and cut surfaces were not examined. The histological section proved to be the most satisfactory method of examination; and it was considered important to prepare both acid-fast and hæmatoxylin and eosin sections in each case. In those instances where histological examination raised any questions of doubt, another series of sections was made. Space does not permit us to give a detailed record of the cases, but briefly stated the results obtained were as follows:—

1. Ninety-five cases showed no bacteriological evidence of tuberculosis.
2. Five cases (Nos. 30, 35, 53, 74, and 90) showed typical giant cell systems.
3. Two of these (Nos. 30 and 53) showed acid-fast bacilli morphologically identical with tubercle bacilli.
4. No positive findings were obtained either in films from crypts or cut surfaces, or from guinea-pig inoculations. Unfortunately, the deposit obtained from the tonsils of one of the two cases showing bacilli was not inoculated into guinea-pigs.
5. The histological lesions in the five positive cases were beneath the crypts of the tonsil, thereby corresponding to the "focal crypt" type of infection recorded by Weller.
6. No family history of tuberculosis was obtained in any of the five positive cases.
7. Incidentally it was noted that three cases (Nos. 40, 52, and 71) showed minute multiple abscesses of non-acid-fast bacteria. This question of the inter-relation of septic infection and the tubercle bacillus we regard as very important, and it will form the subject of our inquiry in another series of a hundred tonsils, upon the examination of which we are now engaged.

Conclusions.

1. Five per cent. of unhealthy tonsils associated with enlarged cervical glands were found to show histological lesions of tuberculosis (giant cell systems). Two per cent. contained morphologically typical tubercle bacilli. These results agree closely with those obtained by other workers in general routine examination of tonsils.

2. Failure to obtain any positive results when large quantities of tonsillar tissue were injected into guinea-pigs is difficult to explain. Considerable care was taken at the autopsies of these animals, and in each case naked-eye evidence was not considered sufficient. Films were always made from the splenic pulp, and from the site of inoculation or any other suspicious lesion which existed. Three explanations of this failure are possible: (1) the tubercle bacilli, being very few in number, were lost in the manipulations of centrifugation, &c.; (2) the lymphoid tissue had effectively dealt with invading tubercle bacilli; (3) the tubercle bacilli were of low virulence (? bovine).

3. Pending a more thorough inquiry now being carried out in a second series of cases, we would tentatively suggest that the chain of events in enlarged tonsils with cervical adenitis is as follows: (*a*) enlargement of tonsils from chronic septic absorption from crypts and unhealthy surfaces of tonsils, followed by (*b*) cervical adenitis due to toxæmia; and (*c*) implantation of tubercle bacilli on the already enlarged unhealthy tonsil, with (*d*) subsequent absorption of bacilli along the lymphatics from tonsil to cervical glands. This process is probably slow and insidious, and the infecting tubercle bacilli are few in number. And, of course, presumably not every enlarged tonsil goes on to stages (*c*) and (*d*).

Inasmuch as the march of infection is normally from the tonsil towards the cervical gland—as indicated by the anatomical researches of Wood,[6] Poirier,[7] and others—the correct surgical procedure would appear to be removal of the tonsil rather than of the cervical glands. Our clinical experience during the past few years further supports this view, so that we now look with disfavour on primary operations on the glands. If the tonsils are properly enucleated it will be found that in a large number of cases the glands tend to disappear; in some cases the operation on the tonsils may cause the glands to break down, in which case aspiration with a suitable syringe is all that is required, and the remainder of the gland undergoes absorption, but should a sinus persist one or two doses with X rays will usually suffice to produce a cure without any disfiguring scar.

A STUDY OF DYSENTERY IN THE FIELD.

WITH SPECIAL REFERENCE TO THE CYTOLOGY OF BACILLARY DYSENTERY AND ITS BEARING ON EARLY AND ACCURATE DIAGNOSIS.

BY JOHN ANDERSON, M.A., B.SC., M.D., CH.B. GLASG.,

CHIEF ASSISTANT TO MISSION OF LONDON SCHOOL OF TROPICAL MEDICINE TO BRITISH GUIANA.

Introductory.

HAVING been attached to a casualty clearing station which landed on Suvla Bay at the beginning of August, 1915, and remained there till the evacuation in December of the same year, I had an opportunity of studying dysentery from the clinical point of view during its period of maximum prevalence, at a time when the morbidity rate from this disease had a very critical bearing on the military situation. The clearing station was afterwards moved to Egypt, and during the three succeeding years had to deal with troops which included always a residue of the Gallipoli force together with reinforcements which were continually arriving from temperate as well as tropical climates. In this way I was enabled to collect material and make notes during three subsequent dysentery epidemics—namely, those of the autumn of 1916 on the Suez Canal, of 1917 in the Sinai desert, and during 1918 in various parts of Palestine.

This paper therefore embodies the results of work during my four years' experience of dysentery in the field. Observations during the first two years were necessarily confined to clinical and statistical phenomena. In 1917 a laboratory was attached to the casualty clearing station and from that time pathological records were always available. Special attention has been given to the subject of early diagnosis based upon the cytological examination of the cellular exudate.

STATISTICS.

The importance of the disease under discussion, in its relation to military operations, is shown by the figures (Table I.) collected from the returns of the casualty clearing station on Suvla Bay in 1915.

While the Imperial Forces were being concentrated in Egypt, that is, during the comparatively quiescent period from January to December, 1916, I was out by Biaggi,[1] Marfan,[2] and others, may be due to a close relation of the causes of these two diseases.

Causes of Adenoid Vegetations.

Essential Causes Overlooked.—On the subject of adenoid vegetations, as they were termed by Meyer in his classical description, much has been written, but their essential cause has, in the main, been overlooked; and lacking a clear understanding of the cause of this hyperplasia of the pharyngeal tonsil, efforts at prevention must be ill directed and ineffectual. But an experience of many years and of a large number of cases teaches me that the essential ætiological element can be clearly differentiated, not only with great advantage to methods of prevention but also with an increase of understanding of the numerous complications of this common and serious condition.

Causes according to Rhinologists.—StClair Thomson,[3] in his remarkably clear and comprehensive text-book, mentions heredity, status lymphaticus, climate, and catarrh. Ballenger[4] refers to the exanthemata. Tilley[5] believes in heredity but quotes Osler on the influence of disturbances in the lymphatic system. Ball[6] lays stress on the exanthemata, particularly measles, whilst Greville Macdonald[7] many years ago pointed out the influence of cold and damp climates, the frequency with which the Jewish race is affected, and, in common with many other observers, mentioned the influence of frequent cold-catching, although he, like most others, thought that this latter might be an effect rather than a cause. Indeed, this is one of the vicious circles so familiar to all rhinologists: adenoids cause catarrh and catarrh causes adenoids.

Causes according to Pediatrists.—H. Campbell[8] thinks that hyperplasia of the pharyngeal tonsil is part of a general hyperplasia of adenoid tissue throughout the body—i.e., status lymphaticus—due to a defect in the plasma resulting from intestinal indigestion caused by imperfectly salivated food. Cautley,[9] whilst attaching some importance to the vicious circle of adenoids and catarrh, believes bottle-feeding and rickets mostly to blame. He thinks almost all children with adenoids suffer from rickets, but that rickets may be present without adenoids. Pritchard[10] believes that Mellin's food, which is largely maltose (the penultimate stage in the digestion of starch) renders children particularly liable to the disease. Stuart Low has, however, pointed out that adenoids are extremely common in breast-fed children.

Symptoms and Sequelæ of Adenoid Vegetations.

In the compass of an article it will be impossible to do more than tabulate the symptoms of adenoids, which are classified by their production of (1) nasal obstruction, (2) reflex phenomena, (3) secondary affections, (4) constitutional changes.

1. *Nasal Obstruction.*—The posterior naso-pharyngeal wall in many subjects presents a plane surface; in a few it is protuberant over the situation of the second and third cervical vertebræ, and in the latter cases a moderate degree of enlargement of the pharyngeal tonsil causes obstructed respiration. In other cases a large mass of adenoid tissue, infiltrated with the products of inflammation and giving rise to effects other than obstruction, may be sunk in a recess. In infants stenosis causes convulsions, laryngo-spasm, and vomiting; they are said to swallow their tongues and fight for breath. In older children are apparent mouth-breathing, snoring, breathlessness, slowness at meals or bolting of food, and alterations in the voice, which becomes "dead." "Clapham Common" becomes "Claphab Cobbod." These patients are said to speak through the nose, which is precisely what they do not do. The most pleasing quality of the human voice depends upon the naso-pharyngeal passage being free and its walls smooth. The mouth is dried by the passage of air, and thirst results. The presence of muco-pus behind or below the soft palate is always pathognomonic.

2. *Reflex Phenomena.*—Such are paroxysmal cough, sneezing, stridulous breathing, laryngo-spasm, asthma, chorea, convulsions, epilepsy, nocturnal enuresis, restlessness, stammering, and stuttering. To relieve most of these symptoms—even epilepsy—by operation is a matter of daily occurrence; in obstinate recurring colds with attacks of dyspnœa, and in cases of nocturnal enuresis, results of operation are remarkable.

3. *Secondary Affections.*—The commonest and most important complication is the affection of the ear. More than 60 per cent. of patients with adenoids are more or less deaf. Inflammation spreads through the Eustachian tubes and may extend through the tear duct, leading to conjunctivitis and other ocular troubles. The appearance of stupidity is due to the open mouth, to deafness, and to deficient oxygenation of the blood. Gastric disturbances are caused by the extension of catarrh into the stomach, and by the swallowing of affected mucus—hence dyspepsia, anorexia, morning nausea, and vomiting. Cervical adenitis, at first simple inflammatory hyperplasia, but apt to become tuberculous, is another important secondary affection.

4. *Constitutional Changes.*—The upper jaw undergoes a striking alteration in shape, which many observers ascribe to rickets. It is usually bent upwards, but sometimes forwards. The normal flattish Norman arch becomes Gothic; this upward bending brings the alveolar edges of the jaw closer together; the teeth become crowded and irregularly set. In some cases the incisors and canines appear one in front of the other. The upward displacement also obstructs nasal breathing, for the roof of the mouth is the floor of the nose; in this manner deflection of the septum nasi is accounted for. Alteration in the shape of the jaw also accounts for the characteristic "adenoid-facies." Chest deformities arise from impeded nasal respiration, particularly where oral breathing is also obstructed, as by enlarged palatine tonsils. Inspiration draws in the lower ribs with retraction or depression of the manubrium sterni, or the ribs are drawn upwards along the costo-chondral margins, and the child becomes pigeon-breasted. Besides these changes, I have frequently noted lateral curvature of the spine, and in an experience of well over a thousand cases have almost invariably found falling of the plantar arch with the production of marked flat-foot. According to Reinhardt, 17 per cent. of United States recruits were rejected for flat-foot alone—an indication of the extent to which that disability exists among the people of a vigorous nation. Other important disabilities are occasioned by the interference in education and physical development brought about by repeated attacks of feverish colds, often mistaken for the preliminary stage of measles and constituting—when the outer members of Waldeyer's ring of lymphatic glands are affected—the so-called glandular fever. Extension of catarrh or inflammation into the Eustachian tubes, with consequent deafness, may partly explain the fact that many school children of this type occupy the lowest positions in their classes. Unfitted by their disabilities for games, the young subjects of adenoid growth frequently become soured by misunderstanding and their sense of deficiency in comparison with other children. They are seldom heard whistling or singing. In an institute devoted to the treatment of rickety children, Biaggi[11] found 90 per cent. had adenoids, while according to Marfan[12] all adenoid children are the subjects of rickets. Deformities of jaw, spine, feet, and chest—catarrh of the naso-pharynx extending to the ears, nose, larynx, lungs, stomach, and intestines—what are these but symptoms of rickets?

Causes of Rickets.

According to most authorities the causes of rickets are chiefly dietetic. Bottle-feeding, starchy food, and other improper alimentation are mostly held to blame. But, as previously mentioned, Stuart Low[13] pointed out the common occurrence of adenoids in breast-fed children, whilst according to Pritchard[14] Mellin's food renders them particularly liable to the condition.

The Catarrhal Side of Rickets.—R. Hutchison[15] quotes with approval two sayings of Sir Wm. Jenner's: first, "Rickets is the most common and in its indirect results the most fatal of all the diseases which peculiarly affect children"; and secondly, "It would be as reasonable to regard rickets as a disease of the bones only, as it would be to regard typhoid fever as merely a disease of Peyer's patches." And Dr. Hutchison remarks, "You must remember there is a visceral side as well, which so far as effects upon life are concerned, is more important than the mere deformities due to alterations in the bones" and "The visceral changes consist first and chiefly of catarrhs affecting the lungs, stomach, and intestines."*

Rickets and adenoid vegetations were both known long before Meyer and Glisson described them. Reference to the paintings of the Renaissance or to the sculptures of antiquity will show the characteristic "adenoid facies," while Hippocrates frequently referred to the disease; he wrote, "those who suffer from headache and running ears have a high arched palate and irregular teeth."

---

* Several of the photographs illustrating Dr. Hutchison's work on children's diseases are very characteristic of adenoids.

amœbic variety. Taking the bacillary cases at the very minimum, that is, those in which Shiga's bacillus or the Flexner Y bacillus were isolated and gave the correct biological and agglutination tests, the numbers are:—

Bacillary dysentery	116, or 95·9 per cent.
Amœbic dysentery	5 ,, 4·1 ,,

If we take the bacillary figures at their maximum, that is, including all diagnosed from a microscopic examination of the cellular exudate provisionally as bacillary dysentery, then the numbers are:—

Bacillary dysentery	385, or 98·7 per cent.
Amœbic dysentery	5 ,, 1·3 ,,

Either of these findings can be taken as a significant indication of the relative importance of the two main types of dysentery in the field.

In 1918 the troops had advanced well into the hills of Palestine, where the water difficulties of the previous year were practically at an end, where the climatic variations were less suited to the rapid increase of flies, and where the conditions of life generally were less foreign to men from the Dominions or the United Kingdom. The result was, that from a military point of view, dysentery became a disease of secondary importance and at no period of the year did it acquire the significance of an epidemic. For the greater part of the year I remained attached to No. 3 Military Laboratory, which had moved up with the advancing troops, and the total examinations of fæcal specimens for the 12 months did not exceed 2000.

In the late summer and autumn a widespread malarial infection threw a heavy strain upon all the laboratories, and little time could be spared for the culture of fæces, so that dysentery statistics are not as complete and telling as they were in the previous years of the war. Out of 2000 examinations the cases diagnosed as true "dysentery" numbered 708. Of these only 80, or 11·3 per cent., were diagnosed as amœbic, and 628, or 88·7 per cent., as "probably bacillary." A certain number of the latter were cultured and in a small proportion B. Shiga and B. Flexner Y were definitely isolated.

Note.—Under the heading of B. Flexner Y I have included the classical mannite-fermenting bacilli. The slight differences between the original Flexner[1] strain and the Y bacillus of Hiss[2] and Russel are so evanescent that for all practical purposes they can be disregarded. Both are agglutinated in moderate dilution by the specific sera issued by the Lister Institute.

CYTOLOGY.

The special investigation regarding the cytology of the stools of bacillary dysentery, with a view to establishing a differential diagnosis as near the front line as possible, was carried out chiefly during the period of highest incidence in 1917. At that time the casualty clearing station with the adjacent laboratory was situated about ten miles behind the active troops, and patients were usually under observation within from one to three days after the commencement of their illness. The rule was that every patient admitted with diarrhœic symptoms was allotted a clean bedpan, and his first stool after admission was immediately taken down to the laboratory, where the microscopical examination of the fresh specimen was carried out often within 15 minutes of defæcation. A likely piece of the stool was selected and transferred by means of a platinum loop from the bedpan to a clean slide. A cover-glass was then superimposed and gently pressed down so as to give an even transparent film of a thickness sufficient to allow the free movement of any contained entamœbæ.

Classification of Cells.

The microscopic picture in an early case of dysentery is always a striking one, on account of the typical cellular exudate presented, and it is perhaps convenient to describe here the differential features of the characteristic cells and organisms found therein.

1. *Cells derived from the gut wall*:—(*a*) *Squamous epithelial cells.*—These are derived from the margin of the anus, are usually of horseshoe shape, and have the characteristic large oval nuclei.

(*b*) *Columnar epithelial cells.*—These are derived from the inner coating of the intestinal wall, are usually isolated, but are sometimes found in orderly clumps. Owing to osmotic pressure in the liquid stool they are often pear-shaped and the rounded nuclei are usually easily identified.

(*c*) *Endothelial cells* may be recognised in at least three distinct varieties. (i.) *Plasma cells.*—These are larger than mononuclear leucocytes and are oval in shape. The protoplasm is not refractile and there is a large oval nucleus usually ex-centrically placed. (ii.) *Macrophage cells.*—These are derived probably from the endothelial lining of capillary walls, vascular as well as lymphatic. They are polygonal when in clumps but usually are isolated and of rounded shape. In size they are generally larger than any other cells in the stool, measuring 15–30 μ in diameter, or even more, and have a large well-defined nucleus of reticular structure and ex-centric in position. The cytoplasm is not refractile but is often vacuolated and may contain red blood corpuscles, leucocytes, and lymphocytes—that is, they are phagocytic. Their exact appearance is dependent to some extent upon the degree of osmosis which has taken place. The size and shape of these cells and the presence of included particles sometimes render it a difficult matter to differentiate them from entamœbæ, but the motility and refractility of the latter are usually conclusive, and in the living state there should be no great difficulty. (iii.) *Irritation or tissue mast cells.*—These are irregular in shape and about the size of a leucocyte. The nucleus is ill-defined and the protoplasm coarsely granular. It is difficult to differentiate these cells from eosinophiles until they are stained.

2. *Cells derived from the blood.*—There are usually large numbers of red blood corpuscles in all varieties of acute dysenteric stools. The white cells are classified according to the nomenclature used in most text-books:—(*a*) Polymorphonuclear leucocytes; (*b*) large mononuclear leucocytes; (*c*) small lymphocytes; and (*d*) eosinophile leucocytes.

3. *Pathogenic entamœbæ.*—The *Entamœba histolytica* is now accepted as the sole causal agent in amœbic dysentery, and while different phases in its life history, such as encysted or tetragena forms and minuta forms are occasionally met with in stools that appear normal, the vegetative or active entamœba is present in all acute cases of the amœbic type.

The Cellular Exudate in Bacillary Dysentery.

The exact degree of reliance which may be placed upon a diagnosis of bacillary dysentery made from a preliminary examination of the cellular exudate has for some years been a controversial point, but the experience of the epidemics during the war has, I think, definitely proved its value.[1] When a film of the blood-stained muco-pus from the scanty gelatinous stool is placed under the microscope, the most striking feature is the abundance of cells, and the scarcity or absence of digestive débris. The cells found consist of varying proportions of the following types:—

(*a*) *Polymorphonuclear leucocytes.*—These form the majority of the cells in all stages of the disease. They may have the normal fresh appearance of healthy leucocytes, but more frequently they are swollen and altered in a characteristic manner. The cytoplasm undergoes a fatty degeneration, the nuclei become distended and ghost-like, and the cell dies *en masse*. This appearance is very different from that found in amœbic dysentery, where the leucocytes seem to undergo a digestive process and become progressively reduced in size owing to a marginal disintegration.

(*b*) *Other blood cells.*—The red blood corpuscles vary considerably in number according to the stage and the degree of acuteness of the attack. In subacute or chronic cases, where the stool is composed largely of mucus, there may be an entire absence of red cells in the field, whereas in amœbic dysentery they are present in nearly all cases.

Lymphocytes and large mononuclear leucocytes are present in insignificant proportions, while eosinophiles are very seldom seen.

(*c*) *Macrophages. Endothelial cells.*—These cells form a small proportion of the total exudate, but their size and characteristic appearance mark them out for special attention. Like the polymorphs, they are found in various stages of degeneration, the cytoplasm becoming granular, vacuolated, and then hyaline; the nuclei becoming granular, distended, and finally broken up and scattered as irregular fragments throughout the cytoplasm.

(*d*) *Epithelial cells.*—Either columnar or squamous. In the early inflammatory stage of the disease, there may be very few of these cells, but in the later desquamative phase they are found often in large numbers.

(*e*) *Plasma cells and irritation cells.*—Present in small variable proportions, depending apparently on the depth to which any ulceration of the gut wall has taken place.

---

[1] Willmore and Shearman, THE LANCET, 1918, ii., pp. 200–208.

of lounging follows. The affected subject stands with the body-weight chiefly supported alternately on one leg and on the other. The plantar muscles and ligaments participate in the general muscular flabbiness; therein lies the cause of flat-foot. Lateral curvature of the spine is due to the same habit of lounging. Standing with the weight mainly on one foot it will be observed that unless a compensating curve in the spine is introduced the whole body is thrown into a slanting position, one hip is raised higher than the other and the spine-bending, unconsciously performed to bring the head into a position over the middle line of the body, becomes a natural sequel. Catarrhal conditions extending into the larynx, trachea, or bronchi render themselves obvious by unmistakable symptoms. But the extension of these morbid processes into the stomach, bile-duct, and intestines, occurring far more frequently, is infinitely more insidious.

Hitherto the cause of rickets has in the main been held to be dietetic; some authorities on pediatrics hold that adenoids are also due to alimentary disturbances. It has also been pointed out that even if the two conditions are separate and distinct—about which there is at least an element of doubt—the gastric disturbances and defective assimilation held to be the causes of rickets may be due to the catarrhal condition of the mucous membrane lining the alimentary canal, rather than to starchy food. Catarrhal jaundice in adenoid subjects, particularly in those who suffer from attacks of asthma, is frequently observed. Catarrh of the stomach is obviously sufficient to account for dyspepsia, anorexia, morning sickness, and vomiting. Extension of catarrhal inflammation into the stomach and intestines accounts for many of the symptoms of adenoids and rickets, and has in my opinion a much more pernicious influence than that caused by the swallowing of infected mucus. Colyer[22] claims that: (1) micro-organisms developing in the adenoid area and directly infecting the alimentary tract, favour the production of intestinal toxæmia; (2) adenoids lead through lethargy and constipation to intestinal toxæmia.

Whilst I do not agree with the observer, mentioned by Colyer, who stated that 95 per cent. of all diseases result from intestinal toxæmia, the latter condition is certainly responsible for very many. An American writer drew attention to the frequency with which appendicitis follows adenoids; Watson-Williams[23] has quoted several cases of this sequence in his own practice, and I have also met with several examples. In one instance it was decided to operate on a boy aged 7, who, suffering from adenoids, suddenly developed an acute attack of appendicitis. In consultation it was agreed, as there seemed no fear of dangerous complications, to wait till the attack had subsided and then remove the appendix. The boy recovered; his parents declined to sanction the abdominal operation pending the development of further symptoms, so I removed the adenoids. It is now 12 years since this operation was performed; there has been no recurrence of the appendicitis and the patient has enjoyed good health ever since.

Conclusion.

To recapitulate: Here we have naso-pharyngeal catarrh extending into the alimentary canal and affecting both digestion and assimilation; exaggerated lymphocytosis and swollen lymph glands rapidly losing their protective influence owing to fibroid changes; the swallowing of large quantities of infected mucus, a drain on the system from the over-production of lymphocytes causing anæmia—to say nothing of the abnormal secretion of the connective-tissue element containing mucin and of the lessened alkalinity of the blood.

The chief cause, excluding the exanthemata, is the mainly disregarded frequently-recurring colds.

S. ROODHOUSE GLOYNE, M.D. LEEDS, D.P.H. LOND.,

PATHOLOGIST, CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST, VICTORIA PARK.

THIS research was undertaken with a view to inquiring into the relationship, if any, which exists between enlargement of the palatine tonsils and cervical adenitis. It was hoped also that the work might throw some light on the more general question of the portals of entry of the tubercle bacillus. The importance of the tonsil as a channel of infection was emphasised by our colleague Dr. Hugh Walsham[1] and others many years ago. During the past 20 years much has been written on the subject, and an excellent summary with an extensive bibliography will be found in a recent article by C. V. Weller.[2] This author has collected published records of 4522 tonsils examined, with positive findings as regards tuberculosis in 3·1 per cent. of cases, which agree closely with the findings (2·35 per cent.) obtained by Weller himself in 8697 consecutive cases of tonsillectomy. On the more particular question of the possible relationship between enlarged tonsils and cervical adenitis less extensive inquiries have been made. Mitchell[3] published a series of cases during the war in which he found tuberculosis in 38 per cent. of tonsils removed from children and adults with enlarged cervical glands. Other workers[4] have made clinical and pathological notes of this association of the two conditions, but the exact proportion of tuberculous tonsils found still remains *sub judice*, the figures varying in different published series from 7 to 38 per cent. Is the palatine tonsil a common portal of entry for the tubercle bacillus, and are enlarged and unhealthy tonsils, therefore, generally tuberculous? Or does the tonsil, acting as a filter, become enlarged and unhealthy from septic absorption, and merely receive the tubercle bacillus from time to time as a secondary invader? These questions have an important bearing on both the pathology of tuberculosis and the surgical treatment of the unhealthy tonsils and cervical adenitis. On the pathological side questions are naturally raised, not only as to the portals of entry, but also as to the reaction of tissues to the tubercle bacillus; whilst on the clinical side the surgeon is required to decide whether the unhealthy tonsils or the enlarged glands, or both, should be removed.

Selection of cases for examination.—Only cases with both unhealthy tonsils and enlarged glands were included in this investigation. In some instances the tonsils were small and embedded, and in others large and prominent; similarly the glands were in some cases small, firm, and discrete, and in others soft and much enlarged. In a few cases the glands had already been treated for tuberculosis. A record was made in each case as to the possibility of infection from some other member of the family. The cases were all drawn from the laryngological departments of St. Thomas's and Victoria Park Hospitals.

Operation.—In all cases the tonsils were removed complete in their capsules, either by dissection or by the blunt guillotine method. The personal technique of these operations has been described by one of us (W. G. H.) elsewhere[5]; it is therefore unnecessary further to refer to it.

Laboratory examination.—Four methods of investigation were employed in each case: (1) Films of muco-pus from the crypts were stained by the usual the bacteriological records must differ very widely from those of a laboratory behind the front line where specimens can be examined possibly on the same day as the man first appears on "sick parade." It has been stated that bacillary dysentery is a self-limiting disease, and whether treatment has been rigidly carried out or not, the clinical and microscopical picture has generally undergone fundamental changes in 10 or 12 days. On the other hand, amœbiasis, unless specifically treated, is notoriously chronic and progressive. The onset is slow and insidious, and for the first few days an examination of the stool in an advanced laboratory may reveal nothing definite. By the time the patient reaches the base, if no emetine has been administered in the meantime, the symptoms are usually well marked, and the pathogenic amœbæ are found without much difficulty. It is not surprising therefore to find variations in the records of different laboratories.

2. The freshness of the fæcal specimen bears a very close relationship to the proportion of positive bacteriological findings compared with the total number of stools examined. Ceteris paribus, the percentage of positive findings reaches its maximum when the laboratory is attached to an advanced field unit, and the bacteriologist can select his specimen directly from the bedpan within half an hour after the stool has been passed.

In order to determine the rate at which dysenteric bacilli disappear from the fæcal specimen, I carried out a series of experiments with some typical stools, and came to the conclusion it was rarely possible to recover, by cultural methods, the specific bacilli from a motion that had been passed eight hours previously.

The practical side of this question may be demonstrated by a few figures taken from the returns of the laboratory with which I was connected in 1918. Here the specimens were sent in from various medical units, most of which were situated at some distance away. Portions of the stools were placed in fæces tubes, and sent to the laboratory by post or by messenger, and frequently an interval of from six to 24 hours had elapsed before the examination was made. Out of 900 specimens examined by culture during the year, only 75, or 8·3 per cent., gave definitely positive results. Of these 75, organisms of B. Shiga type were isolated in 58 cases, and B. Flexner Y in the remaining 17. The results should be compared with the findings of the laboratory during the autumnal incidence of dysentery in 1917 (vide Table). During that period the conditions for successful culture were ideal, because the bacteriological camp was adjacent to the casualty clearing station and bedpan specimens were carried to the laboratory immediately they were passed. Out of 194 specimens cultured under such conditions, 116, or 60 per cent., gave positive results. Of that number, 56 were of B. Shiga type and the remaining 60 were B. Flexner Y.

SUMMARY AND CONCLUSION.

In conclusion, as the result of personal experience of epidemics of dysentery in the field, I would lay emphasis on the following points:—

1. The clinician and the pathologist should be as constantly associated as the surgeon and the anæsthetist.

2. The laboratory should be in close proximity to the source of material.

3. Considering the vicissitudes which surround the isolation of specific dysentery bacilli, much more stress should be laid on a diagnosis founded upon the characteristic cellular exudate. The most important factor in the treatment of acute dysenteric conditions is time, and as a provisional diagnosis by this method can be made at least 24 hours before the bacteriological report is ready, the advantage to the patient is incalculable.

AN UNUSUAL CASE OF INJURY TO THE PETROUS BONE.

BY H. LAWSON WHALE, M.D., F.R.C.S. ENG.,
OTOLOGIST TO THE HAMPSTEAD GENERAL AND TO THE LONDON TEMPERANCE HOSPITALS.

THIS case has not hitherto been reported because it seemed better, in view of the remarkable history, to await the subsequent issue before comment.

Lieut. R. D. C., aged 27, was wounded at Loos in March, 1915. A piece of shrapnel traversed the right cheek, nasal cavities, and both maxillary antra; en route it destroyed the right eye. It was recognised that the shrapnel had lodged in the depth of the petrous bone; but here it caused no local symptoms. And so, although the patient underwent several beneficial nasal and plastic facial operations, the missile had designedly been left undisturbed. On Nov. 11th, 1919, he contracted influenza, very soon complicated by left otitis media. On Dec. 15th he was urgently driven 30 miles to London, and staggered in, very ill, to my consulting-room. Mastoid tenderness and œdema, headache, and mild pyrexia presented an obvious picture of acute mastoiditis. A stereoscopic skiagram taken at once by Dr. N. S. Finzi showed the foreign body 1 in. deep to the skin surface on the same horizontal line as the mastoid antrum, and ¾ in. anterior to it, ⅝ in. superior to the external auditory meatus and the temporo-maxillary joint, and about equidistant from both, evidently lodged in the body of the petrous bone. As regards otorrhœa, the history was that this had now ceased for five days, and that previous to its cessation the discharge had been of a rusty colour, containing a few minute black specks which might have been metallic.

Operation.—An operation was performed next morning, Dec. 16th, Dr. D. H. Fraser anæsthetising. The mastoid antrum and cells were full of pus. Bony necrosis extended so far downwards to the mastoid apex and forwards above the ear that the ordinary post-aural incision had to be prolonged down to the digastric fossa behind and anterior to the pinna in front. The outer attic wall was found to be diseased and was resected; also a small part of the body of the petrous bone immediately superior to the external semicircular canal. There was now a large horseshoe-shaped cavity extending from the digastric fossa behind to within ½ in. of the posterior zygomatic root in front; and since the tegmen antri, the posterior wall of the mastoid process, and part of the tegmen tympani had been resected during the operation, the greater part of this large cavity was bounded peripherally by dura mater. The lateral sinus was evidently healthy. By careful search no fistula could be found which might reveal the position of the shrapnel. At this stage the stereoscopic skiagram was again investigated; bone was then cautiously gouged away from the petrous. The shrapnel was found, as nearly as could be surmised, in the concavity of the superior semicircular canal. After its removal projecting spicules of bone were curetted away in various situations and the cavity drained as for a cortical mastoid operation. Throughout the whole procedure the membrana and the region including the annulus tympanicus had been left untouched, and the posterior bony meatal wall cut away only at the top sufficiently to give free drainage to the attic region, as in a "modified" radical mastoid.

Convalescence was slow but uncomplicated. Eight weeks later a meatal flap was cut and turned back into the cavity; this was henceforth drained by the meatus, the post-aural wound being sutured. After another three weeks the patient went to Eastbourne in charge of a nurse. In May, 1920, five months after the first operation, he was playing golf. On his pre-war handicap of 8 he finished, in a bogey competition at Ashdown Forest, all square with bogey, winning the second prize. Golfers will note that he had only one eye, the left. Since that time his health has been in all respects normal. The epithelialised mastoid cavity has always remained quite dry, the membrane healed, and the cosmetic result perfect. And, with the right (sound) ear excluded by a noise-apparatus, he hears a whisper with the left (injured) ear at a distance of 30 feet.

SOUTH-WESTERN POLYTECHNIC INSTITUTE.—A conversazione will be held on Friday, Nov. 18th, from 7–10 P.M., at the institute, Manresa-road, Chelsea, London, S.W. The lecture rooms, laboratories, studios, and workshops throughout the institute, together with the equipment and apparatus, will be open to inspection.

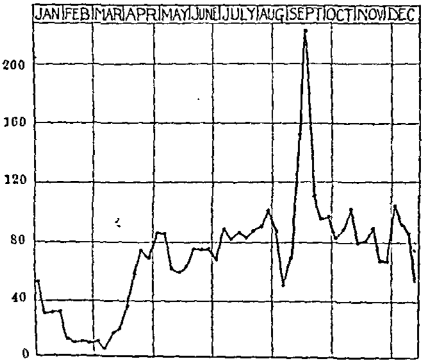
afforded an opportunity for making a more comprehensive epidemiological survey of the disease and the accompanying chart (Chart 1), though limited in scope, may be taken as typical. By this time pathological laboratories had been established in the most important centres, such as Cairo, Alexandria and Port Said, and the figures quoted are all supported by bacteriological data.

CHART 1.—*Incidence of Dysentery in 1916. Weekly Rate per 100,000 Strength.*



The first quarter of 1917 was a period of rapid military progress, and the climatic conditions under which the main body of the army lived were almost ideal from a hygienic point of view. Food was excellent; flies were seldom seen; there was no call for exhaustive work on the score of military necessity; intestinal disease had practically disappeared. At the end of the spring a very strenuous campaign was initiated in front of Gaza. The weather became uncomfortably hot; the forces were physically exhausted; the water supply was a matter of difficulty and flies began to abound. During the period of active operations the casualty clearing station was flooded with surgical cases, but towards the end of April the admissions were practically all medical cases, of which intestinal conditions accounted for the great majority. A field laboratory was by this time attached to the clearing station, and during the period April 25th to May 8th 470 diarrhœic cases were examined bacteriologically, with the following resultant diagnoses:—

Amœbic dysentery	8
Bacillary dysentery (bacilli proven) ..	55
Lambliasis	1
Acute diarrhœa	415
Total	470

The bacillary findings again were subdivided as follows:—

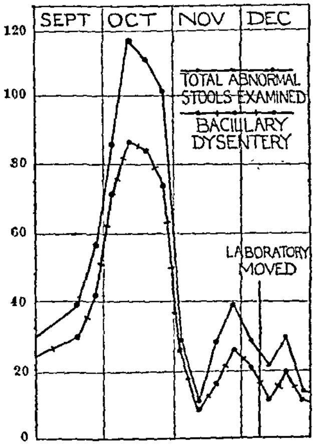
No. in which organisms isolated were		
	B. Shiga ..	31
	B. Flexner Y ..	6
	Not specified ..	18
	Total	55

Taking only the true dysenteries found in this series—namely, amœbic 8, bacillary 55—the relative proportion would be: amœbic dysentery, 12·7 per cent., bacillary dysentery, 87·3 per cent., a result which approximates the percentage recorded as the average for all the laboratories in the previous year.

Creditable as these results are, considering the difficulties under which the work was performed, they do not fully represent the true position. Dysentery bacilli were isolated from only a small proportion of the specimens submitted for examination, and amongst the 415 cases diagnosed as "acute diarrhœa" there must have been a large proportion of bacillary infections.

From the middle of May till the middle of August, 1917, the troops had a period of comparative rest, and as the great heat militated against the spread of flies, there was very little sickness of an intestinal nature. The usual autumnal rise in dysentery commenced about the end of August and reached its maximum in mid-October (see Chart 2). During this period, No. 3 Military Laboratory (officer commanding, Captain P. Manson-Bahr, R.A.M.C.) was attached to the casualty clearing station, and I had the privilege of combining bacteriological investigation with the clinical work in the hospital marquees.

CHART 2.—*Dysentery: Epidemic Rise in 1917. Figures per Week from One Casualty Clearing Station.*



A careful study of this autumnal rise in the dysentery rate afforded some significant statistics, and these have been summarised in Table II., covering the period of highest incidence, that is, during the six weeks ending Nov. 3rd.

TABLE II.—*Figures during Period of Highest Incidence, Sept. 23rd to Nov. 3rd, 1917.*

Total No. of abnormal stools examined	501
Simple diarrhœa	95
Flagellate diarrhœa	16
Amœbic dysentery	5
Bacillary dysentery, provisional diagnosis ..	385
Cultured	194
B. Shiga isolated	56
B. Flexner Y isolated	60

A striking feature in Table II. is the marked preponderance of the bacillary as compared with the

The Blood Sugar Content.—The estimation of the blood sugar had been made by the micro-chemical method described by Dr. Wallis and Dr. C. D. Gallagher in THE LANCET, 1920, ii., 784.

Glucose Tolerance Test.—Dr. Wallis said that the method of applying this test used by him was as follows:—

> A light meal was given in the early morning, which consisted of one egg and tea or coffee with no sugar; three hours later the urine was collected and the amount of normal urinary sugar and blood sugar estimated. 50 g. of glucose in 150-200 c.cm. of water were given, and the blood sugar was estimated again a quarter of an hour and half an hour after the sugar had been consumed, and the urine as well as the blood sugar was estimated one hour and two hours after.

Curves had been plotted of these results and the patients appeared to fall into four distinct groups besides the normal controls. There appeared, moreover, to be a correspondence between the curves of blood sugar and the nature of the disease causing the glycosuria. Dr. Wallis differentiated: (1) a thyroid pancreatic group; (2) severe glycosuria; (3) renal glycosuria; (4) hyperpituitary cases. A striking feature was that cases of glycosuria in pregnancy fell into the fourth group.

Hyperpituitarism in Pregnancy.—Dr. Wallis felt convinced that in the glucose tolerance test we had the best, and at present the only means of detecting minor degrees of hyperfunction of the pituitary body. He said that this explanation of transitory glycosuria in pregnancy would appear to be the most reasonable and that the results are certainly suggestive. Dr. Wallis referred to cases published by him in association with Dr. F. A. Roper (1912) and Dr. Geoffrey Evans (THE LANCET, 1921, vol. i., p. 70) of intermittent glycosuria of pregnancy, and said that both these cases showed many of the characteristic signs and symptoms of hyperpituitarism. In acromegaly the signs of hyperpituitarism were so marked that there was little difficulty in diagnosis, but in milder cases the glucose tolerance test seemed to Dr. Wallis the only one available. Acromegaly was often accompanied by glycosuria in the early stages, often transient in character and frequently occurring without relation to diet; polyuria was frequently exhibited by these cases and extreme lassitude. In pregnant women intermittent glycosuria unaffected by diet, associated with normal or only slightly raised blood sugar, also occurred. Dr. Wallis spoke of the changes in the pituitary body during pregnancy and advanced arguments in favour of his contention that certain signs and symptoms exhibited by pregnant women could be attributed to excessive functioning of the pituitary body. He showed glucose tolerance curves illustrating the resemblance between known cases of hyperpituitarism and intermittent glycosuria in pregnant patients. The outcome of his investigation was that these cases were best left alone. They were able to tolerate 50 g. of glucose without the passage of abnormal amounts of sugar in the urine, and restriction of carbohydrates in their diets was unnecessary and might be harmful.

Severe Glycosuria in Pregnancy.—Every case of glycosuria in pregnancy should be regarded as a potential case of diabetes mellitus until proved otherwise. The presence of lactose should be excluded; if the fasting blood sugar showed a value over 0·2 g. per cent. of glucose there was evidence of gross disturbance of carbohydrate metabolism. Dr. Wallis quoted cases illustrating the value of blood-sugar estimations in glycosuria of pregnancy. The glucose tolerance test was not yet available as a means of prognosis, insufficient data having been collected.

Discussion.

Sir WILLIAM WILLCOX asked Dr. Wallis whether he had considered the thyroid gland in connexion with the glycosuria of pregnancy. This gland was known to vary in size with changes in the genital organs, and, in Sir William Willcox's opinion, was probably a factor to be considered. As to the severer cases showing evidence of diabetes mellitus, Sir William Willcox discussed the importance of acidosis as shown by the presence of acetone and diacetic acid in the urine. Acidosis might be present apart from diabetes—as in pernicious vomiting. Sir William Willcox asked whether diabetic patients were as susceptible as normal patients to acidosis. The conditions under which pregnancy should be allowed to continue were of importance. In America, apparently, patients suffering from severe forms of diabetes were allowed to go to term on special diets, but in Sir William Willcox's experience where there was low carbohydrate tolerance, such as 10 g. or 20 g. it was unwise to allow the pregnancy to continue.

Dr. P. J. CAMMIDGE said that Dr. Wallis's apparent assumption that dextrose was the only sugar, apart from lactose, to be found in the urine was contrary to his own experience. In looking through his cases, Dr. Cammidge had found that about 50 per cent. were passing dextrose, 22 per cent. lactose alone, and 24 per cent. lævulose. He had repeatedly been asked to see pregnant women said to be developing coma, in whom there was much sugar in the urine but the blood sugar was normal. Of the urinary sugar ½ g. or 1 g. proved to be dextrose and the rest lævulose. If these patients were made to fast they became ill and even comatose, whereas if given a full carbohydrate diet, with much toast, they improved rapidly. Dr. Cammidge had been converted to a belief in the value of dextrinised starch under these conditions, and quoted cases in which this treatment had proved successful. Only those cases showing dextrose in the urine benefited from starvation. Dr. Cammidge expressed himself unable to follow Dr. Wallis's classification. His own classification included a pancreatic group who improved with fasting and a hepatic group who became better when the liver was relieved by the decrease of proteins and increase of carbohydrates in the diet.

Dr. GEORGE GRAHAM differed from Dr. Wallis in his interpretation of the blood-sugar curves. The curves of cases described by Dr. Wallis as suffering from glycosuria of pregnancy resembled those shown by cases of mild diabetes. Dr. Graham considered that patients who showed glycosuria during pregnancy were comparable with those who showed glycosuria when attacked by carbuncles and with those recently described by Castellani in whom glycosuria was present only during a malarial attack. Any acute illness might lower the blood-sugar tolerance. Dr. Graham quoted a patient who had temporary glycosuria when suffering from impetigo. He deduced from these analogous conditions that the diminution of sugar tolerance arose from the extra strain put upon the metabolism by pregnancy. He was much interested in Dr. Cammidge's observations on the frequency of the appearance of lævulose.

Dr. HERBERT WILLIAMSON asked for an explanation of the association of glycosuria and hydramnios. He spoke of the occasional effect of maternal glycosuria on the infants, quoting a case in which he had been associated with Dr. Cammidge where the patient was delivered of three live children who died within a few hours of birth in a state of apparent coma.

Dr. CAMMIDGE mentioned that these children were abnormally large, a circumstance not unusual in cases of true maternal diabetes. The purely theoretical explanation that occurred to him was that these infants when in utero were accustomed to a medium of excessive sugar and could not adapt themselves to normal metabolic conditions after birth.

Dr. J. D. BARRIS asked Dr. Wallis what effect the administration of pituitary extract had on sugar tolerance.

Dr. WALLIS, in reply, said that the thyroid gland probably did play a part in the glycosuria of pregnancy since the actions of all the endocrine glands were balanced against one another. The cases investigated were those who showed dextrose. Dr. Wallis agreed with Dr. Cammidge that lævulosuria is connected with hepatic function. In his experience pancreatic glycosuria, as demonstrated by patients suffering from carcinoma of the head of the pancreas, was always fatal. In reply to Dr. Graham, Dr. Wallis objected

Cellular Exudate in Amœbic Dysentery.

The differential diagnosis of the two main types of dysentery would seem to present little difficulty if one is dealing with ordinary uncomplicated cases; the microscopic examination in a fresh specimen presents a very different picture from the one just described. The most striking feature here is the scantiness of the cellular exudate unless, as is sometimes found, the specimen consists of almost pure blood from ulceration through the wall of a vessel. With regard to the cells that are present, those consist of:—

(*a*) *Polymorph leucocytes.*—These are rarely seen in their normal condition. A proteolytic process is obviously at work, and they are usually partially ingested, giving them a "mouse-eaten" appearance. The process commences at the periphery of the cytoplasm and progresses until only remnants of the nuclei remain scattered throughout the film—a very different picture from that in the bacillary type where the leucocytes die by a massive toxic necrosis.

(*b*) *Other blood cells.*—These also exhibit differences that are equally striking. The lymphocytes are relatively increased in number and have the same degenerated appearance, while the eosinophiles are markedly increased. The prevalence of eosinophiles is so noticeable that it might almost be regarded as a pathognomonic sign of the presence of entamœbæ.

The red blood corpuscles also show a remarkable phenomenon. In bacillary dysentery the red cells are isolated as in diluted normal blood, but in the amœbic type they are generally clumped together in small groups of from two to eight, suggesting some agglutinative effect. This phenomenon, so far, does not appear to have been mentioned by other observers.

(*c*) *Macrophage cells.*—Very rare in uncomplicated cases of amœbic origin.

(*d*) *Epithelial cells.*—Usually present together with plasma cells, but there is nothing to distinguish them from those found in the desquamation of bacillary origin.

(*e*) The vegetative *Entamœba histolytica* or its encysted form. This clinches the diagnosis of amœbic dysentery, but where that organism cannot be found—and Wenyon[3] has pointed out that the chances of not finding it are considerable—then in a case presenting a pathological picture such as has just been described one is justified in reporting it as "probably amœbic dysentery."

The recognition of the outstanding features of the cellular exudate, and their great importance as a factor in the rapid diagnosis and early treatment of two diseases differing so widely as regards their pathology and therapeutic requirements, naturally calls for a closer investigation of this field. With that object in view I arranged to make careful observations in a series of suitable cases admitted to hospital during the epidemic rise of 1917.

In each case clinical notes were taken on admission and the first stool was carried at once to the laboratory, where the fresh specimen was examined macroscopically as well as microscopically. In the absence of pathogenic entamœbæ, a provisional diagnosis of bacillary dysentery was made. Another film was prepared, fixed, and stained for a subsequent and more prolonged examination. In addition, a piece of muco-pus was spread for culture on a plate of MacConkey's medium, and the bacilli of dysentery subsequently recognised by the usual serological and biochemical tests. In carrying out the former tests, Garrow's agglutinometer[4] proved to be of great practical value.

Differential Count of the Cellular Exudate.

In each slide 500 cells were counted, and the table of figures (Table III.) gives the results in 15 cases of acute bacillary dysentery. The diagnosis in each case was established by the isolation of colonies which (*a*) gave the correct sugar reactions, and (*b*) showed agglutination in the appropriate serum. The first eight cases of the series have been arranged according to the stage of the disease; the last seven were taken in the order of admission. Other bacillary cases were counted, but as the results were all so uniform, it was considered that the 15 selected would be sufficient to give an average estimate.

In order to emphasise the significance of the figures in the differential diagnosis of bacillary dysentery, I have drawn out a contrast table (Table IV.) to show the average cellular content of an amœbic stool. Five cases were selected at random, in all of which the *Entamœba histolytica* was found in the active vegetative form, and in none of which were any dysentery bacilli recovered from cultures. The five cases are placed in the order of admission, and in this table a further column has been added to include the cells undergoing pyknosis. In each slide 500 cells were again counted, and a percentage struck.

TABLE III.—*Details of Cellular Exudate in Acute Bacillary Dysentery. Differential Counts.*

TABLE IV.—*Details of Cellular Exudate in Acute Amœbic Dysentery. Differential Counts.*

Case No.	Per cent. polymorph leucocytes.	Large mononuclears.	Lymphocytes.	Eosinophiles.	Epithelial cells.	Plasma cells.	Pyknotic cells.
1	5·6	0·8	3·4	2·4	2·0	3·4	82·4
2	4·8	1·0	2·2	4·4	2·2	2·4	83·0
3	5·6	0·2	1·8	2·4	1·4	1·6	87·6
4	10·8	0·6	2·4	2·0	0·8	0·8	82·6
5	10·6	0·8	2·6	4·8	0·2	0·8	80·2
Average	7·5	0·7	2·5	3·2	1·3	1·8	83·0

In each case the organism found was active *E. histolytica*. Macrophages, no result.

A comparison of Tables III. and IV. brings out the following salient features:—

Bacillary Dysentery.

1. The preponderance of polymorph leucocytes, which constitute on an average 90 per cent. of the total cellular exudate.
2. Eosinophile cells were seldom or never present.
3. Macrophages were present in limited numbers, averaging about 2 per cent., but their size renders them very conspicuous.
4. "Pyknotic" bodies were not found in any of the 15 cases under review.

Amœbic Dysentery.

1. The small proportion of polymorph leucocytes, the average content being only 7½ per cent.
2. The presence of eosinophiles is a conspicuous feature, the number varying from 2 per cent. to nearly 5 per cent.
3. Macrophages were not found in any of the five cases of this series.
4. "Pyknotic" cell remnants were present in all cases, their average number reaching the very high proportion of 83 per cent.

Essentials of the Problem.

After studying the effect of varying conditions on the fæcal constituents in a number of cases I am of opinion that the whole problem can be narrowed down to an examination of two points: (1) the proximity of the laboratory to the active troops: (2) the freshness of the fæcal specimen.

1. If a laboratory is situated at the base, and, as not infrequently happens, cases do not reach the base hospital until their tenth or twelfth day of illness,

Reviews and Notices of Books.

HEALTH OF THE INDUSTRIAL WORKER.

By EDGAR L. COLLIS, M.D., and MAJOR GREENWOOD, M.R.C.P. With an introduction by Sir GEORGE NEWMAN, K.C.B. London: J. and A. Churchill. 1921. Pp. 450. 30s.

IN their preface to this work the authors point out the lack of a book which deals at all adequately from the standpoint of hygiene with the profound changes in the lives of civilised people during the past century and a half consequent upon the rise and development of modern industry, and whilst disclaiming the possession of the erudition necessary for the task of writing such a book, refer to the experience in industrial hygiene which they individually possess. They express the belief that they "have made plain how great is the influence of employment upon general health, how many are the opportunities presented in industry for studying conditions which lead up to divergencies from health—divergencies which, when neglected, pass into disease, how ready to hand are means for improving the workaday life of the productive classes, and how important to the whole of preventive medicine are lessons learnt in the school of industrial hygiene." No one, after reading the book, will quarrel with such a belief. The importance of the whole matter is beyond question, and the authors' book should do much to advance its study. The introduction by Sir George Newman shows a broad minded and wide grasp of the subject matter.

Two chapters in Part I. deal with Industry and Health, and a Review of Industrial Legislation, and these are excellent. It is very desirable to clear away the misapprehension existing in the minds of so many that the position of industry is novel, and that the remedies suggested to cure its ills to-day are new. It should be made apparent that the industry of to-day is merely a link in a chain, and depends upon what has gone before, just as it must influence what may come after. In view of recent happenings it will scarcely be a matter for surprise, though it may be of regret, to learn that in the progress recorded the reasonable recommendations of important committees and Royal Commissions have been passed by unheeded, whilst attention has been paid to subjects pressed to the front by uneducated or biased voices. Chapters III. and IV. deal with the Utilisation of the Statistical Method in Industrial Preventive Medicine, and the Effect of Industrial Employment upon Health as Indicated by Vital Statistics. It will occur to some readers that these might well have been shortened, since the book is not suitable as a text-book for serious students of statistics, whilst in uninstructed hands statistical methods are likely to lead to error. While a briefer outline might have been sufficient, especially when, as the authors indicate, the book is addressed to the novice, familiarity with statistical procedure is now so necessary to workers in public health that there is much to be said for any inducements to its study.

Part II., dealing with Industrial Activity and Fatigue, Tuberculosis and Industry, Cancer, Accidents, and the Industrial Employment of Women will prove of value in facilitating that general dissemination of knowledge, existing indeed but to a large extent hidden away in Government publications. These are not inaccessible, but their study is apt to be a difficult matter, and many will be grateful to have a handy manual dealing with so new a subject as fatigue. It must not be forgotten, however, that much of the work still awaits confirmation and amplification, and that even the methods employed in arriving at present results have not been free from criticism. With psychological arguments also this is true, and they cannot be relied on as sure guides, though as indications they may be useful. We cannot altogether agree with the authors in their condemnation of common sense as a guide in administration (p. 204). In the absence of facts bearing directly upon the question in hand, common sense may prove an excellent guide, whilst to proceed in any course without it would be foolish. Indeed, we think that in one of the instances cited common sense would have suggested to anyone familiar with the workers' home life that women on night work would, if possible, engage in domestic duties during the day, and thus tire themselves unduly. It is common knowledge, if not common sense, that domestic claims must be uppermost in the minds of most women, and these will always sacrifice themselves in the interests of the home whenever the opportunity presents itself. Is it, therefore, correct to say that the existence of this "interfering social influence" "could not be determined without careful investigation?"

The authors are on sure ground in Part III., which deals with the Feeding of the Industrial Worker, Food at the Factory, the Use of Alcoholic Beverages by the Industrial Worker, Ventilation, Lighting, Washing and Sanitary Accommodation, Drinking Water, Working Clothes, Cloak Rooms and Seats, and everyone will be glad to make use of their experience. The treatment of feeding is likely to be especially useful, since it lies at the base of industrial efficiency. One passage puzzles us. The authors say (p. 252): "This branch of the subject is so commonplace, it offers so few scientific novelties, such scanty occasions for the exercise of intellectual ingenuity, that we cannot expect the reader to be greatly interested." They cannot be meaning to imply that it is only subjects which offer "scientific novelties," and "occasions for the exercise of intellectual ingenuity" that prove attractive: those of their readers who matter are in search of something more than this! For the rest, the value of the factory canteen is fully recognised, and the chapter on alcohol, though short, is perhaps as much as could be looked for. The subject is one of immense difficulty and beset with prejudice. Industrial drinking cannot be treated effectively by itself, but only as a part of the general hygiene of the worker.

In Part IV., which includes chapters on Labour Turnover, Supervision of Industrial Health, and Reclamation of the Disabled, the writers are dealing with familiar subjects, and give us valuable material from which to come to decisions. The same words of commendation might be employed of the work as a whole. It will be useful, especially to the industrial administrator, who, though often necessarily ignorant of the subjects treated, is anxious to learn and to act upon sound information.

PRINCIPLES OF IMMUNOLOGY.

First edition. By HOWARD T. KARSNER, M.D., Professor of Pathology, and ENRIQUE E. ECKER, Ph.D., Instructor in Immunology, Western Reserve University, Cleveland, U.S.A. London: J. B. Lippincott Company. 1921. Pp. 309. 21s.

THIS book has been written as "a concise statement of the facts and more important hypotheses concerning resistance to infection," and being designed for those readers who have no facilities for mastering the technical details of such an intricate subject, the work has been confined to fundamental principles without any elaborate descriptions of experiments. That the authors have produced so clear an account of their subject in face of the difficulties of their self-imposed task is no mean achievement.

Early in the book the authors face the vexed problem of theories of immunity, and although apparently not prepared altogether to discard Ehrlich's side-chain theory, they recognise that Ehrlich was much influenced by the status of chemistry which prevailed at the time the theory was enunciated and that modern researches on colloids have profoundly modified our views. A number of these researches are quoted (p. 49), particularly those emphasising the difficulties which surround the question of union of toxin and antitoxin. The authors find the question of specificity the most difficult to explain on a colloidal

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

Exhibition of Cases and Specimens.

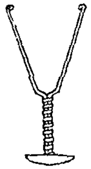
A MEETING of this section of the Royal Society of Medicine was held on Nov. 3rd, Prof. HENRY BRIGGS, the President, being in the chair.

Mr. A. E. MORTIMER WOOLF showed a specimen of Double-ruptured Interstitial Ectopic Pregnancy.

Dr. W. J. O'DONOVAN showed a

Gold-Button Contraceptor.

He said that a patient, aged 26, who had been married for 12 months had consulted him for pruritus vulvæ of six months' duration. There was no history of menorrhagia or severe dysmenorrhœa, but there was a slightly malodorous vaginal discharge. Vaginal examination revealed a hard foreign body across the cervix which Dr. O'Donovan had removed by a firm pull and now showed to the section. The patient said it had been inserted by a doctor in New York soon after her marriage for a fee of £20. The device consisted essentially of a cup-shaped gold button, which fits over the cervix with a stem of coiled gold wire the thickness of piano wire, which plugs the cervical canal, and two prolongations which spring apart and which in the uterus would extend up to the Fallopian internal ostia and by their springing apart would fix this appliance permanently in place. A central hole in the cup permits menstrual and other fluids to pass through. Dr. O'Donovan considered it unnecessary to dwell upon the dangers inherent in such an instrument, which would be appreciated by members of the section.



Gold button used as contraceptor. Half actual size.

Dr. A. E. GILES said that a patient had asked him to insert one of these pessaries as a contraceptive. On making inquiries from the makers he ascertained that they were sold at two guineas each and were advertised as the latest cure for sterility. Dr. Giles strongly deprecated the use of such an instrument for any purpose.—Dr. NORMAN HAIRE said that the instrument was really an abortifacient and in Germany was sold as such. Since the instrument was hollow, conception might occur; he had heard that abortions following its use were often septic. He considered the instrument very dangerous.

Dr. GORDON CRANSTOUN read a short communication on a case of

Cystic Adenoma of the Uterus.

Unfortunately, the specimen had been destroyed but microscopic sections were available. The patient was a nullipara, aged 45, with a two years' history of gradual enlargement of the abdomen and increasing dyspnœa. Menstruation had been regular until eight months before admission to hospital when it had ceased. A diagnosis of unilocular broad-ligament cyst was made, and Dr. J. Fairbairn operated on April 13th. On exposure the cyst wall was found adherent to the parietal peritoneum, omentum, and gut, and efforts to separate it resulted in rupture and the escape of large quantities of opaque brown fluid. On exploration of the pelvis the uterus was found to be enlarged and to contain what appeared to be several fibro-myomata, while the surrounding structures were adherent. Pan-hysterectomy was performed. The mass removed consisted of a uterus enlarged by the presence in its wall of three connected masses resembling fibro-myomata about the size of tangerines, of which one apparently arose from the left upper cornu of the uterus. It appeared to be interstitial and composed of uterine tissue, and presented an ovoid flattened surface to the abdomen forming a kind of plateau. The wall of the cyst was continuous with the edge of this plateau and the point at which a section was cut was composed of uterine tissue containing spaces filled with degenerated blood-clot similar to that covering the surface of the plateau. The degeneration and distension of the tumour, according to Dr. Cranstoun, might have started centrally, and the dilatation on the abdominal side caused by the lack of resistance, so that the upper part of the tumour had gradually stretched to form the wall of an immense cyst, which contained three or four gallons of fluid as well as altered blood-clot. The right tube and ovary and the left ovary were normal, also the left tube, the proximal end of which, however, appeared to be lost in the wall of the cyst. The patient recovered and is now well. Dr. Cranstoun said he had shown the sections because this type of tumour was apparently very rare. Cystic adeno-myomata of small size had been recorded, but this one occupied the whole abdomen.—Dr. J. FAIRBAIRN said that the material that came out of the cyst was dark and treacly and might have been a secretion from the glandular masses.—Mr. GORDON LEY agreed that the microscopic sections looked like those from an adeno-myoma.

Dr. R. L. MACKENZIE WALLIS read a paper on

Glycosuria in Pregnancy.

He said that he proposed to divide the cases of glycosuria in pregnancy into two groups: 1. Transient or intermittent glycosuria. 2. Severe glycosuria and diabetes mellitus. Most of his work had been concentrated on the first group. The investigation of cases comprised: (1) the detection and estimation of normal and abnormal amounts of sugar in the urine; (2) the variations in the blood sugar in normal non-pregnant women and in pregnant women; and (3) the application of the glucose tolerance test as a means of diagnosis.

Method of Estimating Normal Urinary Sugar.—The normal urinary sugar content was too small to be detected with the ordinary reagents, and, moreover, other substances present in the urine might possess a reducing substance of their own and at the same time interfere with the reducing powers of the sugar present. Dr. Wallis said that after a long search he had found a means of removing these substances without interfering with the sugar present and proceeded to describe the following method which had been perfected with the help of Dr. P. J. Bose:—

The urine is collected at hourly or two-hourly intervals, and the estimation carried out as soon as possible after collection. If this is impossible toluol is added to the urine as a preservative, and in this way the urinary sugar keeps for a considerable time. One c.cm. of the urine is precipitated by 2 c.cm. of the phospho-tungstic reagent made up to contain 2 per cent. P.T.A. in 5 per cent. sulphuric acid. A dense pigmented precipitate appears and the mixture is now thoroughly shaken. The whole is made up to 10 c.cm. by adding 7 c.cm. of distilled water, shaken, and filtered. The filtrate is of a clear watery colour, and is found to be free from creatinin, pigments, and all substances likely to interfere with the detection and estimation of sugar. One c.cm. of this clear filtrate is heated for six minutes in a boiling water bath with 2 c.cm. of an alkaline copper solution. At the end of this period the tube is taken out, and treated with a solution of phospho-molybdic acid. The presence of sugar is revealed by the appearance of a deep blue colour. In order to estimate the amount of sugar present in the urine the colour produced by the standard solution of glucose treated in a similar manner with that of the urine is compared in a good colorimeter.

Thus a large number of estimations had been made upon every variety of urine. So far a clear filtrate with the phospho-tungstic acid reagent had always been obtainable, no matter how deeply pigmented the urine might be. In comparing the results obtained on a large number of individuals, the constancy of the amount of sugar in normal urine was striking. It exceeded 1 g. a day on an ordinary mixed diet, and the percentage of sugar in the urine corresponded curiously closely with that regarded as normal in blood—viz., 0·08–0·1 per cent.

especially the small models provided in the so-called universal machines, is strongly condemned, because these currents are not perfectly constant, and therefore cannot be used when a strong current is required. The authors show that the frequent failure to treat successfully many cases of pain due to neuralgia is due to the inability to apply currents of sufficient strength when these dynamos are used, because the patient is unable to bear a strong current if it is not absolutely constant.

This book would be more suitably addressed to those readers who have some experience of medical electrology. The general practitioner in this country will find it too large for the purpose for which it has been designed. The specialist will, however, find much that will interest him, for the descriptions are clear and the illustrations good.

The Sahara.

By Pierre Loti. Translated from the French by Marjorie Laurie. London: T. Werner Laurie. 1921. Pp. 216. 10s. 6*d.*

M. Loti shares with Kipling and M. Claude Farrère the faculty of making his readers feel that if they go out of the door they will at once be in the country about which he is writing. This feeling was very obvious in Madame Chrysanthème and is equally obvious in the book now before us, in which M. Loti gives us an unforgettable picture of the loneliness of life for Europeans in Senegal, of the witchery and magic of the land and of the horrible fascination which its manners and customs can and do exercise. Readers of Kipling will recollect that in his grim story called the "Mark of the Beast" he begins by saying, "East of Suez, some hold, the direct control of Providence ceases; Man being there handed over to the Gods and Devils of Asia. . . . ." The same thing, mutatis mutandis, holds good for Africa, especially the western part thereof, for whether it be simply the call of the bush, or that blessed word "environment," or hypnotic suggestion, or some form of devilry, it is an undoubted fact that men do get caught up into a very unpleasant set of circumstances, and M. Loti's story gives a vivid picture of the fate of a spahi who was thus enmeshed. It is intensely real and subtle.

The translation is good, but why should the translator have changed the title from "The Romance of a Spahi" to the Sahara? for the book *is* the romance of a spahi and has but little to do with the Sahara.

Colloids.

Rôle des Colloïdes chez les Etres Vivants. Essai de Biocolloïdologie. Nouvelles Hypothèses dans le Domaine de la Biologie et de la Médecine. By Auguste Lumière. Paris: Masson et Cie. 1921. Pp. 312. Fr.16.

The author herein presents a theoretical discussion based upon certain of the properties of colloids. He epitomises his views in the statement that life is conditioned by the existence of the colloidal state; illness and death are caused by its flocculation or precipitation. There are many other properties of colloids than those specially selected for his theory, and it would have been of more value if these properties had also been brought into the discussion and carefully examined before the theory had been brought forward. It cannot be doubted that the colloidal state of the living cell and the colloidal state of the circulating and other fluids will be affected by extraneous reactions, such as the injections causing anaphylaxis, but other changes, especially the chemical, involving the production of the actual toxin, are more probably the real cause. The change of the colloidal state is the effect produced by these substances. The theory now put forward is of some interest and worth consideration, but further experiments, as pointed out by the author, are required. The little book contains a useful list of references to anaphylaxis and colloids and some very excellent illustrations.

Burdett's Hospitals and Charities, 1921.

The Year Book of Philanthropy and Hospital Annual. London: Scientific Press, Ltd. Pp. 1027. 17*s.* 6*d.*

This year book is now so widely known, and has been found so useful and reliable, that notice of a new issue seems almost superfluous. The customary concise and valuable information is given concerning hospitals and all other forms of medical, nursing, and convalescent establishments, not only in this country, but also in the Dominions and Colonies and in the U.S.A. Considerable revision has been made in the directory of institutions; the names of those which have remained closed for two years or more have been omitted, and particulars of charitable institutions which have not supplied information for some years have been curtailed. To the military and naval section have been added the hospitals for which the Ministry of Health is financially liable, with a definition of the class to which each hospital belongs. The chapter and table concerning convalescent homes are omitted, pending a time when more of these institutions shall have returned to normal conditions. A list of hospitals approved by the Ministry of Health for the treatment of venereal diseases has been added to the index. It may occur to some readers that "an exhaustive record of charitable work for the year" is not absolutely complete without a reference to the Homes of St. Giles, the one establishment in this country devoted to the treatment of leprosy.

Ophthalmology.

Grundriss der Augenheilkunde. Second edition. By Dr. C. H. May and Dr. E. H. Oppenheimer. Revised and translated into German by Dr. Oppenheimer. Berlin: August Hirschwald. 1921. With 266 figures and 22 coloured plates. Pp. 427. M.60.

This, one of several moderate-sized text-books of ophthalmology published in Germany since the war, is the German edition of a book originally published in America, and is considerably enriched by figures and coloured plates from the American edition. The authors' task appears to have been for the most part adequately performed, though in some parts the matter is scarcely up to date. How long shall we continue to find in text-books the traditional classification of iritis into syphilitic, rheumatic, and gouty, without any recognition of the importance either of gonorrhœa or of septic infection in its causation? In the operative treatment of glaucoma, trephining of the sclera is allotted only a few lines in small print. The account of toxic amblyopia is insufficient and the section on colour-blindness is written on traditional lines. It is a pity that the binding is so bad that the pages fall asunder as soon as they are cut.

JOURNALS.

Quarterly Journal of Medicine (October, 1921). —R. Coope: The Sugar Content of the Cerebro-spinal Fluid and its Diagnostic Value, especially in Encephalitis Lethargica. In the first accounts of encephalitis lethargica in 1918 the cerebro-spinal fluid was described as showing no marked abnormalities, but in the 1920 epidemic several French observers found an increase in its sugar content. Accepting 60 to 70 mg. sugar per 100 c.cm. fluid as normal, 54 per cent. of the 11 cases of encephalitis lethargica examined by the author showed an excess of sugar, but as in a series of 69 cases of other diseases, chiefly insanities, an excess of sugar was found in 53 per cent., this cannot be regarded as diagnostic. In 15 cases, however, of tuberculous and acute meningitis, all showed a reduction in sugar content, often to a considerable degree.—R. A. Guy: Observations on the Percentage of Sugar in the Blood of Atrophic Infants. The blood sugar was determined in the case of 18 marasmic infants, using 43 normal infants as a control. The wasters showed a slightly lower percentage of blood sugar, but no relationship was established between to the name of mild diabetes for cases who did best when left alone, as this name implied that they required treatment. To Dr. Williamson he pointed out that the pathology of hydramnios was still obscure. To Dr. Barris Dr. Wallis said that the effect of pituitary extract on sugar tolerance had not been established, but that adrenalin in repeated doses had a certain effect.

SECTION OF MEDICINE.

AT a meeting of this section of the Royal Society of Medicine held on Oct. 25th, Dr. G. **NEWTON PITT**, the President, being in the chair, Dr. W. W. **PAYNE** read a paper by Dr. E. P. **POULTON** and himself on

Epigastric Pain.

Experiments were detailed arising out of the work of one of the authors, in which it was shown[1] that distension was an important element in the pain of gastric ulcer, and that this pain could be abolished by reducing the intragastric pressure. The method adopted was to pass a Ryle's tube with a bulb on the end of it containing water and connected with a manometer outside the body. Alterations in the level of the manometer gave an indication of the contractions of the viscus in which the bag lay. It was found that pain experienced at the umbilicus and just above it was associated with contraction of the pyloric end of the stomach, the duodenum, or even the jejunum. The latter fact was discovered in a patient in whom pain had returned after performance of a gastro-jejunostomy for gastric ulcer. A feature of special interest particularly from the theoretical aspect was that pain high up in the epigastrium was associated with powerful contractions of the lower end of the œsophagus. The authors regarded this as due to abnormality in a special gastro-œsophageal anti-regurgitation reflex. Contrary to the generally accepted belief they held that activity of the lower end of the œsophagus and not merely contraction of the cardiac opening was responsible for stopping regurgitation from the stomach. The paper was illustrated by numerous diagrams.

Discussion.

Dr. R. **HUTCHISON** thought the authors could not account for all epigastric pain on this hypothesis. It was well known that a child suffering from congenital hypertrophic stenosis of the pylorus, with violent peristalsis visible through the abdominal wall, apparently suffered no pain. He thought there was also a possibility that the pain might cause a reflex contraction rather than the contraction cause the pain.—Dr. **PARKES WEBER** regarded the method as possibly useful in investigating cases of idiopathic dilatation of the œsophagus, so-called cardio-spasm.—Dr. T. **STACEY WILSON** remarked that Sherrington had shown that muscular tone was involved in keeping the intestine patent. When a peristaltic contraction reached a portion of the bowel thus tonically kept open, the opposing muscular actions gave rise to pain.

Dr. **POULTON**, in reply, said that the epigastrium was a large area, and he did not contend that all epigastric pain arose in the way that had been described. He agreed with Dr. Hutchison that the violent contractions in congenital hypertrophic stenosis were apparently painless.

LIVERPOOL MEDICAL INSTITUTION.

THE first ordinary meeting of the session took place on Oct. 27th, Dr. J. E. **GEMMELL**, the President, in the chair.

Mr. **EDGAR STEVENSON** read a note on the

Treatment of Septic Ulcer of the Cornea by Chauffage,

first described to him by Mr. Harrison Butler about 12 months ago. During this year Mr. Stevenson had treated a considerable number of septic ulcers of the cornea by this method with exceptionally good results, and he considered it far better than any other method of treatment. In addition to the rapid healing of the ulcer, an important point was that with chauffage the resulting scar was much thinner than that following healing by any other method.

Dr. G. F. R. **SMITH** read a note on Post-anæsthetic Complications.

Dr. **DINGWALL FORDYCE** read a paper on the

Significance and Treatment of Some Abnormalities of the Urine in Children.

He held that thorough examination of a child includes chemical and microscopical examination of the urine, which may disclose the presence of pus cells and motile bacilli. He said that these are never present in great numbers in a perfectly healthy child, but there are a considerable number of children, probably mainly girls, whose urine is in this condition and who are yet "fairly well." The bacilli belonged to one of the types of the "coli" group, and the exact site of the infection was impossible to determine in young children. Dr. Fordyce stated that the essence of both preventive and "therapeutic" treatment was correct diet and the avoidance or cure of septic foci. A common statement in the text-books was that sugar was rarely found in the urine in children, but in a recent series of 100 unpicked cases of ailing children, evidence of sugar in the urine was certainly present in 10. However slight and fleeting the positive test results may be, an explanation should be sought for them. In a large proportion of cases the presence of a positive test corresponded with indiscretion in diet or digestive disturbance and disappeared on its correction. In other cases a septic process was the cause.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held at the Royal Devon and Exeter Hospital on Oct. 20th, Dr. P. H. **STIRK**, the President, being in the chair.

Sir **JAMES PURVES STEWART** delivered an address on

Delirium.

Classifying his subject in the three divisions of acute delirium, non-febrile toxic delirium, and delirium in organic brain affections, he subdivided these forms of delirium, and then discussed their diagnosis, prognosis, and treatment.

In the discussion which followed, Dr. **RICHARD EAGER**—speaking from his experiences in mental hospitals—considered that acute delirious mania was a very rare condition, and that in the cases which had come under his notice there had been no high degree of pyrexia. Dr. Eager spoke of the value of Stoddart's treatment in this condition. He considered that "senile mania" was often influenced by traumatism, and that "exhaustion psychosis" was often wrongly classified as "delusional insanity." Dr. Eager advocated the early treatment of mental cases in special hospitals regarding certification as an objectionable procedure.—Dr. W. **GORDON** congratulated the lecturer on his classification of the subject. He also described a case of rabies and one of tuberculous meningitis with aphasia. Dr. Gordon discussed the "coloured nightmares" mentioned by Sir James Purves Stewart, and related his own visual impressions during the course of a severe infective illness.—Mr. **NORMAN LOCK** referred to so-called "catheter fever," and the question of a septic causation or an origin from bladder colic.—Dr. F. A. **ROPER** advocated a more extended use of hyoscine in delirium.

Sir J. **PURVES STEWART**, in his reply, agreed that hyoscine in repeated full doses had often proved of great value in the quieting of delirium.

Sir J. Purves Stewart was subsequently entertained at the Exeter and S.W. annual medical dinner, Mr. A. C. Roper, F.R.C.S., being in the chair.

---

[1] THE LANCET, 1921, i., 263.

among the employees examined were found to be the onset of acute infection, constipation, poor hygiene, psycho-neurosis, and eye-strain in the order named. One variety, fatigue headache, is specially described; it occurs as the result of over-work, mental or physical, particularly among persons with unstable vaso-motor systems. The writers call for more extensive study of headache by physicians working in industrial communities.—The scarcity of contributions from this side of the Atlantic in this Anglo-American journal continues to be noticeable.

BIO-CHEMICAL JOURNAL. Vol. XV., No. 3. 1921.—Influence of Free Fatty Acids in the Intestinal Contents on the Excretion of Calcium and Phosphorus, by S. F. Telfer. The absence of bile from the intestine occasioned by biliary atresia and obstructive jaundice leads to no marked reduction of the completeness of the splitting of fats, but to the appearance of a very large amount of fatty acid in the form of calcium soaps in the fæces. The calcium would be normally excreted as calcium phosphate. Under the pathological conditions the phosphoric acid remains free, is absorbed from the intestine, and appears in increased amount in the urine.—Effects of an Unbalanced Diet on the Production of Guinea-pig Scurvy, by G. M. Findlay. The development of scurvy in guinea-pigs deprived of vitamin C is not accelerated by feeding excess of either protein, fat, or carbohydrate, but death occurs rather earlier on an excessive protein or carbohydrate diet than on a fat diet.—Oxygen Consumption of Amphibian Muscle and Nerve, by N. K. Adam. The author's apparatus shows very clearly the regular consumption of oxygen by a resting muscle and nerve, the largely increased rate of absorption after stimulation of the muscle and a very small and doubtful increase as a result of stimulation of the nerve.—A Critical Study of the Methods of Estimating Cholesterol and Allied Substances, by J. A. Gardner and M. Williams.—A Source of Error in the Colorimetric Methods for the Estimation of Cholesterol in Tissue Fats, by J. A. Gardner and F. W. Fox.—Specific Electrical Resistance of Frog's Muscle, by W. Hartree and A. V. Hill. The specific conductivity of a muscle at any temperature is the same as that of a sodium chloride solution of 0·36 per cent.—i.e., half the isotonic strength—at the same temperature. This seems to be due to a hindrance of the diffusion of the sodium and chlorine ions by membranes and colloidal structures in the tissue.—Stability of Tryptophan in Baryta Hydrolysis, by H. Onslow; Nature of the Substances Precipitated by Mercuric Sulphate from Hydrolysed Caseinogen. with reference to the Estimation and Isolation of Tryptophan, by the same author.—Method for the Colorimetric Estimation of Carnosine, by W. M. Clifford.—Deterioration of Cotton on Wet Storage, by N. Fleming and A. C. Thaysen.—Nature of the Reducing Substance in Human Blood, by E. A. Cooper and H. Walker. Improvements in MacLean's method of estimating blood sugar are described. Uric acid and creatinine do not vitiate the method. The reducing power of deproteinised blood is usually increased after boiling with dilute hydrochloric acid; this indicates the presence of some hydrolysable complex. But the increase of reducing power so produced is difficult to estimate accurately because the acid tends to destroy the glucose already present. and further, the sodium chloride formed on neutralisation exerts a powerful inhibitory effect on the apparent reducing power of the sugar.—Differential Dialysis of the Antineuritic and the Antiscorbutic Factors, by S. S. Zilva and M. Miura. The antineuritic and antiscorbutic vitamins are found to pass through a collodion dialysing membrane of such permeability that it also allows the passage of such molecules as methylene-blue. neutral red, and saponine.—Relation of the Fat-Soluble Factor to Rickets and Growth in Pigs, by S. S. Zilva, J. Golding, J. C. Drummond, and K. H. Coward. No definite rickets was induced in sucking-pigs fed from birth on a diet rigorously restricted in the fat-soluble factor. The addition of the fat-soluble factor in the form of cream, cod-liver oil, and lucerne to a deficient diet stimulated growth in pigs declining in weight.—Synthesis of Vitamin B by Yeasts (Preliminary Note), by A. Harden and S. S. Zilva. Saccharomyces ellipsoides can synthesise vitamin B when grown on media not originally containing it.—Action of Salts and Non-Electrolytes upon Buffer Solutions and Amphoteric Electrolytes and the Relation of these Effects to the Permeability of the Cell, by D. Haynes. A detailed discussion, partly theoretical, partly practical, of the effects of neutral salts and non-electrolytes on the reaction of buffer mixtures and of the properties of ampholytes. A theory of the permeability of membranes is put forward in which the membrane is supposed to be most readily permeable in the uncharged iso-electric condition. Changes of permeability may then be the result of changes of reaction in the buffer solution which constitutes the liquid phase of the membrane, or of a change in the iso-electric point of the more solid phase.

New Inventions.

A NEW STETHOSCOPE.

I HAVE found this stethoscope a great advantage over ordinary stethoscopes. Its merits are chiefly derived from the fact that the chest-piece is set at a right angle, which allows the instrument to be more readily adjusted and to be used under clothing, so that very little undressing is required. The instrument can be used to examine dependent parts, the heart sounds being more distinctly audible when the patient lies face downward. In the same manner the fœtal heart is best heard, and prostrate and paralysed patients may be thoroughly examined without disturbing their position. In the case of children the chest can be auscultated whilst the doctor stands behind the child, thus tending to prevent crying through fright. In a busy practice this instrument saves much time and gives much information in a hurried examination. It can be used as an ordinary stethoscope by merely unscrewing the diaphragm.

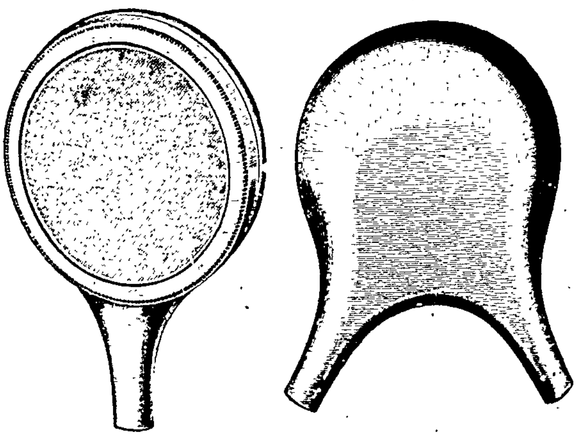


FIG. 1. FIG. 2.

FIG. 1.—Single chest-piece. This may be used with a single tube for those who use but one ear, or it may be connected with a binaural frame with a Y-shaped connexion.
FIG. 2.—Double chest-piece for use with binaural frame.

The chest-pieces can be obtained from all surgical instrument dealers at a cost of 10*s.* 6*d.* each.

WM. C. MINCHIN, M.D., B.Ch., B.A.O. Dub.
Sheerness.

LIEUT.-COL. J. H. DUDGEON, V.D., J.P., of Stainburn, near Workington, has been appointed Deputy Lieutenant for the County of Cumberland.

basis, and we wish that more space could have been found for a full discussion of this aspect of the subject, since it has important bearings on the application of immunological theories to clinical practice. In the subsequent chapters dealing with individual toxins there is a concise description of the Schick test; a fairly full discussion on tetanus toxin viewed in the light of the war researches from 1914 onwards, together with army statistics; and a good account of the phyto- and zoötoxins. Antibodies also receive fairly full consideration. We note the inclusion of a description of Dreyer's method of performing the agglutination test, a full account of iso-hæmagglutinins and blood transfusion, the "typing" of anti-pneumococcal serums, and other recent researches. The discussion on the rôle of complement in immunity is exceptionally full and the Wassermann test enjoys its full prominence, but we could wish the authors had given more consideration to those questions of complement fixation in bacterial diseases—especially tuberculosis—which are giving rise to so much confusion of thought and practice at the present time. The cutaneous tests for asthma are given in detail—indeed, the whole section on anaphylaxis is dealt with comprehensively.

The weakest point of the book—a most unfortunate blemish—is the lack of detailed references. Beyond a short list of text-books on immunity given in the preface, there is not a reference to be found to original sources of information, beyond the authors' names. Some of the illustrations are most helpful, but we do not quite understand why the writers have included in a book dealing with principles and not with laboratory details, illustrations showing how laboratory animals are bled. These are, however, largely matters of detail. Viewed as a whole the book is an eminently sound text-book and can be recommended to the senior student as a safe guide to the fundamental principles of immunity.

PRACTICAL MEDICAL DICTIONARY

Of Words used in Medicine, with their Derivation and Pronunciation, including Dental, Veterinary, Chemical, Botanical, Electrical, Life Insurance, and other special terms; Anatomical Tables of the titles in general use, and those sanctioned by the Basle Anatomical Convention; Pharmaceutical Preparations, official in the U.S. and British Pharmacopœias and contained in the National Formulary; Chemical and Therapeutic Information as to Mineral Springs of America and Europe, and comprehensive lists of Synonyms. Sixth revised edition. By THOMAS LATHROP STEDMAN, A.M., M.D. London: Baillière, Tindall and Cox. 1921. Illustrated. Pp. xii. + 1144. 42s.

WE received this book nearly six months ago, but deliberately delayed our review until we had opportunities of practically ascertaining the merits, and demerits if any, after continued consultation. This is the sixth and revised edition, and our previous notices hold good, but every dictionary, if kept steadily up to date, is in a sense a new book, not so much because many things may have to be added and a few perhaps subtracted, but because, with the march of events in any science like medicine, the relative importance of things alters, and where a long explanatory meaning might have to be appended to a work in the earlier stages of the lexicographer's art, in the later stages a much briefer definition suffices. How carefully Dr. Stedman has discharged what he calls the truly Sisyphean task of a continuous revision is indicated by the fact that, while much that is new has had to be included, suppressions and compressions have only necessitated in the current volume an increase of 20 pages.

Dr. Stedman shows his exactness by removing the numerous mistakes that occur in medical literature between words beginning "ideo" and the words beginning "idio," those beginning "ileo" and those beginning "ilio"; there are a good many authors who might be saved, by consulting pp. 484–485, mortifying little errors, while acquiring useful acquaintance with etymological points. In definitions, also, the dictionary is happy, while its catholicity is shown by the fact that we have practically never failed to find what we were looking for, even when such modern abbreviations as P.U.O. and V.D.H. were in question. It is now necessary to include these abbreviations in medical dictionaries, for they have passed into medical language. Three misprints only have been noted after six months' consultation, and we note them so as to help the author in carrying on for future issues. On p. xi. "Mamely" is given for "namely" in the definition of the abbreviation "sc."; on p. 655 the German "nahr" has the "a" unmodified; and on p. 1061 the editor cannot make up his mind how to spell John Tyndall's name.

As will be seen, we have employed this medical dictionary steadily and with convenience in the course of producing a medical journal, with the result that we are able to commend it, as before, very highly to our readers; but Dr. Stedman will be ill-advised to allow the pressure of new things to compel him to make the dictionary inconveniently large. He may be grateful therefore for the suggestion that some prefixes common to a great many words might appear in a paragraph, with the prefix only printed once, the affixes being assigned to it by hyphens. An examination of the entries under the prefix "laryng-" will reveal what we mean. While the plates are good and useful, space would be gained if some of the textual illustrations were suppressed; many of these can be found in more useful and detailed form in well-known text-books. "Feet" is the plural of "foot," but it seems hardly necessary to mention it—there may be other needless definitions, but we allude to this one with the comment that we have not found any others so clearly unwanted. This is considerable praise when it can be added that the exhaustive sub-title is justified by the contents.

ÉLECTROLOGIE.

By LOUIS DELHERM, Chef du Laboratoire d'Électroradiologie de l'Hôpital de la Pitié, and ALBERT LAQUERRIÈRE, Chef du Laboratoire d'Électroradiologie, Suppléant de l'Hôpital de la Pitié. Paris: A. Maloine et Fils. 1921. Pp. 324. Fr.18.

THIS book is the thirty-first volume of the series "Traité de Pathologie Médicale et de Thérapeutique Appliquée." It has been written, not as a complete treatise on medical electricity, but as a guide to the practitioner who wishes to learn something about the uses of electricity for diagnosis and treatment, and to practise the simpler methods which do not require special experience and elaborate apparatus. In the first part of the book the elementary physical principles are simply explained, together with the various electrical currents and the apparatus which produces them. In the second part, which occupies about three-quarters of the book, the diseases and morbid conditions suitable for electrical treatment are considered and their treatment described. Diseases of metabolism, of the skin, of the digestive tract, of the circulatory apparatus, of the nervous system, and of the uro-genital system are considered in separate chapters. Electro-diagnosis is described in a chapter on the treatment of diseases of the peripheral nerves and the neuralgias. In an appendix the risks that accompany the use of currents from the main and the way to avoid them are explained. The surgical uses of electricity as a means of cauterising abnormal tissue are not described. Bergonié's method of producing artificial exercise by the electrically provoked contraction of the muscles is fully dealt with, and the authors speak highly of the value of this treatment, not so much for the reduction of obesity, but for improving the health of gouty and plethoric individuals. A form of electrical lavage is described in detail, and the authors recommend it for cases of stasis of the colon. It combines mechanical and electrical stimulation of the intestinal muscle. The use of the continuous current obtained from being struck by two things—namely, in the first place, the enormous amount that is now done by the educational authorities in behalf of their charges; and in the second place, the almost unlimited field for effort which remains. The prevalence of dental disease, of ophthalmic defects, of tuberculosis in varied forms, and mental defectivity and abnormality make up an appalling total, even while we can congratulate ourselves upon progress. That these sad things were with us in greater bulk before there was any machinery for their detection or alleviation is undoubted, but the evils being uncharted remained largely unnoticed. Now we all know that the health of our school children is seriously assailed in countless directions, and it is a matter of quick conscience with us to do everything to remedy the ills; for it is to our young that we have to look, more anxiously than ever, to make good the wastage and ill sequences of war. This sentiment is on every lip, but it should also stimulate every action.

We can make no attempt to review seriatim the contents of this closely packed report, nor does the concentrated information in the different chapters lend itself to abstraction or condensation. The report is essentially one that should be read by the medical profession and public alike; if here two things are selected for comment it is because the opportunity offered to the public of coöperation with medicine in remedial measures is very clearly indicated. The problem of the care of the eyes of many thousands of British school children in England from their infancy throughout their school age is a very pressing one. The eyesight of so many is defective that the amount of work here presented to remedial medicine may seem unending. And, no doubt, before the number of the defective can be reduced to a figure representing only the measure of unpreventable default, a great deal of steady and intensive work must be done. It should be done as quickly as possible. Defective vision stands, Sir GEORGE NEWMAN reminds us, in the front rank of all school maladies, for by the eye the child mainly learns, while all methods employed to teach him tend necessarily to increase any existing mischief. Yet it is during elementary school life that every practicable step should be taken to detect and remedy physical defects. School medical officers work to this end with assiduity, but their efforts must be supplemented by a public, the whole of which has to-day received some measure of education, if those efforts are to bear prompt fruit. Medical wisdom may diagnose the form and extent of the physical mischief, may secure proper natural and artificial lighting in the schools, may insist upon the school furniture being of the right sort and rightly placed, and may prescribe the glasses appropriate to the case, but if the parents do not play their part much of this good and costly work will be wasted. If the small patients for whom glasses have been ordered do not obtain them because their parents have taken no pains in the matter, medicine can hardly be blamed if the process of catching up a mass of accumulated evil becomes a lengthy one. This one instance of the provision of glasses shows well how necessary is public coöperation. Where there are satisfactory arrangements for the following-up of children under medical treatment there will be many fewer cases of apathetic neglect. The parents do not really understand how necessary it is that measures for the relief of eye mischief, when their need has been discovered, should be taken immediately. The trials of domesticity press severely upon many of them, but if they can be made to realise the urgency that should mark their share in the treatment of their children, few of them would be backward: The Royal Surgical Aid Society has now come forward with an offer to provide the best English lenses in English metal steel frames at a cost of one subscriber's letter for each pair of ordinary spherical corrections, so that the cost of spectacles, both initial and at renewal, is largely met. In this way a real excuse for the do-nothing attitude has been removed.

An important section of the report is devoted to physical education in schools, which Sir GEORGE NEWMAN has long recognised as one of the most important branches of preventive medicine as well as of education. Organisers of physical training have now been appointed by 79 out of 316 education authorities in England and Wales, and the syllabus of this training, reissued in 1919, has had a circulation running well into six figures. Dealing with the rôle of games in secondary schools for girls, the report sees no reason to anticipate that injury, either immediate or remote, will result if the games are properly chosen and played in moderation, and in these words sets out a conclusion substantially the same as that reached in the recent discussion at the Medical Officers of Schools Association (THE LANCET, Oct. 29th, p. 902). But a warning is given against making undue demands upon the physical strength of the present generation of girls which has not been trained for generations in vigorous bodily exercises of all kinds. The medical officer of the Board of Education seems almost to make an excursion into Lamarckianism when he adds that boys have acquired a tolerance of exertion, a physiological habit of resistance to fatigue which girls have yet had no equal chance of acquiring. Games simpler than hockey or lacrosse—e.g., net-ball and rounders—are found more suitable for pupils at a town school between the ages of 14 and 17. Where no playing field is available, ingenuity and resource on the part of the gymnastic mistress will result in more interest and variety in playground and gymnasium games than these are generally found to possess. All should be directed towards forming habits of open-air recreation and love of pursuits likely to bring girls out of doors and into the fresh air during an after life which for most of them will be of a sedentary character. The results of remedial gymnastics in secondary schools are frankly admitted to have been disappointing, and the intensive treatment of marked abnormalities in a few pupils should be supplanted by small daily classes in corrective exercises for all children needing special attention, the needs of the many taking precedence over those of the few. Attention is called to the work of Fröken FALK of Stockholm, which is largely remodelling gymnastics in the Scandinavian countries where there is a definite reaction against the specialist in physical education alone. A recent decision on the part of the London County Council to go ahead with increasing from 25 to 50 its classes of remedial exercises is in harmony with the spirit of this report, and displays, moreover, that practical coöperation between medical and lay guidance in which the hopes of the future reside.

◆

Defective Diet as a Cause of Sterility.

IN works on sterility the attention of the reader is chiefly drawn to the anatomical and pathological causes of the condition. Very little is said about physiological causes. We might define as cases of physiological sterility those in which there is apparently no obstacle to the union of the gametes, but in which, owing to some faulty characteristics in either the spermatozoa or the ova, union does not take place;

the amount of sugar ingested, and that found in the blood, and the latter does not afford an indication of carbohydrate absorption.—E. E. Laslett: Notes on Four Cases of Paroxysmal Tachycardia. The first, a case of paroxysmal fibrillation of the auricles in a man, aged 46, was considered to be due to excessive tobacco-smoking. It disappeared, to a large extent, when the tobacco consumption was reduced, but tended to reappear with resumption of the habit. The second was a man, aged 48, also a heavy smoker, who suffered from attacks of giddiness, due to paroxysms of auricular tachycardia. On smoking less the attacks disappeared. The third was a man, aged 19, who had been a very heavy cigarette-smoker from an early age. He died shortly after a recurrent attack of tachycardia, which was probably ventricular in origin. The fourth, a man, aged 55, appeared to be a true case of ventricular tachycardia, of which probably only six undoubted cases are on record. Electrocardiographic evidence is not forthcoming in this case.—William Stobie: An Inquiry into the Clinical Manifestations of a Syphilitic Infection upon the Heart. The author endeavours to determine the proportion of cases of heart lesions met with in clinical practice which are due to syphilis. He commences with a brief historical review of the descriptions of syphilitic cardiac lesions, and then proceeds to discuss their pathology and symptoms. He found clinically that in 18 cases of aortic disease 13 gave a history of syphilis, a positive Wassermann reaction, or both. In 15 cases of mitral stenosis 3 gave a positive Wassermann reaction, and of these none gave a history of rheumatic fever, but one had suffered from scarlet fever. None of his 16 cases of mitral regurgitation gave a positive Wassermann reaction, but 4 out of 7 cases of myocarditis reacted positively to this test, and were very suggestive of being syphilitic in origin. A series of 13 cases of congenital syphilis of varying ages was examined, but only one exhibited a cardiac abnormality. In one fatal case of this disease a gumma was present under the endocardium, and spirochætes were found in the pericardial fluid.—H. F. Höst and Rolf Hatlehol: Investigations on the Concentration of the Nitrogenous Metabolic Products in the Blood under Physiological and Pathological Conditions. The authors investigated the nitrogenous blood constituents, using Folin's methods, in 34 healthy and diseased people. The most interesting results were obtained in a further series of 4 cases of kidney disease, each exhibiting uræmic symptoms, which all terminated fatally. The residual N, urea N, uric acid, and creatinin were determined simultaneously and daily up to the time of death. A great and rapid accumulation of blood urea was demonstrated, which could not be explained simply by diminished excretion, and must be in part due to accelerated protein katabolism. The concentration of residual N, urea N, and creatinin was increased up to the time of death, but the most constant feature was the marked ante-agonal increase of creatinin. It appears probable that there is a causal relation between the retention of the N products and the development of the symptom-complex known as uræmia.—J. M. H. Campbell: Some Aspects of Exophthalmic Goitre. The author has endeavoured to trace all the cases of exophthamic goitre treated in the wards of Guy's Hospital between 1908 and 1917. The article is thus an extension of the investigations of Hale White on similar cases treated at the same institution during the years 1888 to 1907 and previously published (*Q. J. of M.*, 1910-11, iv., 89). Of the 127 cases treated 89 were traced by letter up to the time of death, or for periods varying from 4 to 16 years. The author works out the figures for prognosis as approximately 40 per cent. almost cured, 30 per cent. very much improved, 15 per cent. worse or only slightly improved, and 15 per cent. died. The question of treatment is also considered, and it is stated that the final results from thyroidectomy do not appear greatly superior to those of medical treatment, although there is usually a great immediate improvement. Those who received X ray treatment in hospital did not appear to recover more rapidly than those who received only rest and medicine.—E. O'Connor: Critical Review—The Results of Gonorrhœal Infection of the Nervous System. The author, after an exhaustive review of the literature, and an investigation of the records of special and general hospitals in London, is of the usually accepted opinion that nervous complications in gonorrhœa are exteremely rare. Even when they are present it is difficult to prove that they are due to the gonococcus or the gonotoxin. Gonorrhœal cerebro-spinal meningitis has been clinically established, and similarly a gonococcal meningo-myelitis probably occurs. The evidence for the existence of psychoses, neuritis, neuralgia, and trophoneurosis as direct results of gonorrhœal infection is as yet inconclusive.

JOURNAL OF INDUSTRIAL HYGIENE.—An article by C. K. Drinker and K. M. Thomson appears in the August issue entitled "Does the Magnetic Field Constitute an Industrial Hazard?" The research upon which the paper is based is of interest for the scientific way in which it was conducted, even though the conclusions arrived at are negative. Blood and nerve-muscle preparations were exposed to the greatest field strengths obtainable, up to 18,725 c.g.s. lines per square centimetre; and dancing mice were exposed for three months to fields of approximately 2800 c.g.s. lines per square centimetre for an average of 15 hours daily. The methods used and the records obtained are illustrated. None of these experiments gave the slightest evidence of physiological effects from the magnetic field. The experiments utilised *field strengths far greater than those to which workmen are subjected, and, since the tissues employed were those most likely to show vulnerability, it would seem certain that the magnetic field has no significance as a health hazard.*—J. P. Baumberger contributes an article in the September number on Fatigue and Error in a Mental Occupation. The process observed was that of preparing pay-checks which was performed by clerks for a few hours at irregular times on each day; the clerks for the remainder of the time were employed on routine work in the auditing department. The process studied thus provided a ready-made test of fatigue produced by auditing, interposed in the normal course of work. When the rapidity of output was measured at different hours on different days, curves were obtained typical of those observed in studies of industrial fatigue; if the output of the first hour, which exceeded that of the second, be omitted, the curves both for morning and afternoon were of the saddle-back shape; and the output of the morning was greater than that of the afternoon. Errors in preparing the pay-checks were enumerated, when the curve of errors was found to be converse to that of output; and the average of morning errors to be below that of afternoon errors. The results obtained may advantageously be compared with those of Muscio,[1] who has obtained, from medical students and typists, curves with striking resemblance to those of industrial output by charting subjective "feelings of fatigue," as stated by the individuals observed. The conclusions to be drawn from these two pieces of research are that diurnal variations in activity exist which are influenced by meal-times; and that, although we can feel fatigued without being physically tired, "feelings of fatigue" are a close measure of actual physical tiredness.—Headache, which is the most important among "feelings of fatigue," is dealt with in the October number by S. Cobb and D. C. Parmenter. The occurrence of this symptom among a number of employees was carefully investigated, and the conclusion is reached that it is a common complaint among industrial workers, causing in some units as much as 23 per cent. of the cases of lost time, and an average of 10 to 15 per cent. in the mercantile establishments specially studied. The commonest causes of headache

Annotations.

"Ne quid nimis."

NOTIFIED INFECTIOUS DISEASE IN 1920.

A report on the Incidence of Notifiable Infectious Diseases, just issued[1] by the Ministry of Health, gives the figures for each sanitary district in England and Wales during the year 1920. The total numbers, along with the rate per 1000 of population, are thus stated:—

	Number of cases notified.	Rate per 1000 of population.
Scarlet fever	119,490	3·19
Diphtheria	69,481	1·86
Tuberculosis: Pulmonary	61,665	1·65
Tuberculosis: Other forms	15,851	0·42
Small-pox	263	0·01
Typhoid	3,109	0·08
Continued fever	35	—
Relapsing fever	7	—
Pneumonia	38,859	1·04
Cerebro-spinal fever	583	0·02
Encephalitis lethargica	890	0·02
Polio-myelitis	293	0·01
Polio-encephalitis	36	—
Dysentery	1,353	0·04
Trench fever	39	—
Malaria (contracted in England)	32	—
Erysipelas	16,051	0·43
Puerperal fever	2,898	0·08
Ophthalmia neonatorum	10,304	—

No cases of cholera were notified during 1920. There were three cases of plague, two of which occurred in the Port of London and one in the county borough of Liverpool. Two cases of typhus were notified from the port of Weymouth. Of the diseases with marked seasonal frequency the maximum of scarlet fever occurred in the week ending Nov. 13th, of diphtheria Jan. 24th, of typhoid Sept. 18th, of cerebro-spinal fever March 13th and 27th, of polio-myelitis Oct. 9th, and of encephalitis lethargica in the week ending Jan. 1st, 1921. Scarlet fever and diphtheria were each more plentiful by about a third than in the preceding year, encephalitis lethargica by more than one-half. Of ophthalmia 1656 more cases were notified than in 1919 and 3772 more than in 1918. The 1920 rate for ophthalmia was 10·76 per 1000 births. Most of the notifications of dysentery and trench fever related to recurrent attacks in men who had contracted the disease abroad. Similar figures for diseases notified during 1920 in the smaller American cities have just been issued.[2] But in this case the totals are not given, as the returns are admittedly incomplete.

STREET TRADING IN LONDON.

A Departmental Committee is shortly to deal with street trading, and evidence on the following points could with advantage be obtained. In streets used as markets standpipes for the supply of water should be erected. A supply of clean water would be of special value to the vendors of fish, vegetables, and ice-creams, as well as to coffee-stalls. In London a convenient form of standpipe is in Holborn, where it has replaced the use of watering troughs. The free supply of galvanised iron bins to stall-holders has been found to be an advantage in the case of London street markets; very few complaints of nuisance in connexion with such refuse as cabbage leaves, fish offal, &c., have occurred after their issue. Vendors of food should be required to give the address of premises where their unsold food is stored; too often it is in an open yard. To prevent contamination by street dust or domestic animals, food for sale should be placed at not less than 2 ft. 0 in. or 3 ft. from the ground. Articles such as butter, margarine, and cheese, which are not generally cooked or washed before consumption, should be kept covered. Although the same requirement should in equity be made in the case of these articles in shops, yet the same likelihood of contamination does not, in fact, occur as when they are exposed in the open street. Experience shows that sanitary conveniences which are chiefly used by vendors in street markets are a fertile source of complaint unless supervised by an attendant. In streets of tenement houses stall-holders are apt to use the sanitary conveniences and the backyards of the ground-floor tenements, and in consequence nuisances arise. In view of the fact that street stalls can only be run at a profit when placed in streets of a different description—viz., streets with shops where customers are attracted and accustomed to shop—the forbidding of the use of streets containing a large proportion of "houses let in lodgings" would be no hardship to the stall-holders. Women should not be allowed to hawk articles in the streets when accompanied by babies or other young children. In some instances the mother brings her baby with her because the child is ill and requires her attention. Some, at least, of these women actually undertake a daily journey from a distant suburb to the central parts of London to secure a larger sympathetic clientèle. Street musicians are often accompanied by young children, who act as collectors of money; the baby in the cradle on an organ necessarily risks exposure to inclement weather. But it is at least doubtful whether the section of the Children Act prohibiting the exposure of a child in a manner likely to cause him unnecessary suffering or injury to his health, was intended to include exposure of this kind. The duty of dealing with abuses might well be laid on the police who are on the spot. Though we have had the metropolis in our mind during these comments, the abuses to be guarded against may make their appearance in any urban centre.

SCLEROSING NON-SUPPURATIVE OSTEOMYELITIS.

At the recent meeting of the American Medical Association Dr. S. Fosdick Jones,[1] of Denver, read a paper before the Section on Orthopædic Surgery on the rare condition known as sclerosing non-suppurative osteomyelitis, the classical description of which was given by Garrè in 1891, based on his observations in the Tubingen Clinic of Prof. Bruns, although an isolated case had been reported by Kluppel in 1879. In the great majority of cases the onset of the disease is acute, accompanied by a high fever, swelling of the affected limb, pain at the site of the bone lesion, and considerable infiltration of the soft parts; but the skin over the affected bone is not reddened, and there is no formation of pus. As the temperature subsides the swelling of the soft parts disappears, and only the permanent enlargement of the bone remains. The condition must be distinguished from sarcoma of bone, bone syphilis, and solid osteitis fibrosa. Although nocturnal pains in the bone are common to both diseases, the absence of other syphilitic manifestations, the gradual disappearance of the pain, and the negative Wassermann reaction in the blood and cerebro-spinal fluid should serve to distinguish Garrè's disease from bone syphilis. Malignant diseases of bone can be excluded by the initial rise of temperature: absence of glandular enlargement, the infiltration of the soft parts, and the absence of cachexia and rapid loss of weight. In osteitis fibrosa, with or without formation of cysts, spontaneous fracture is the predominant symptom, the temperature is normal, and swelling and pain are not symptoms of which the patient complains. Dr. Fosdick Jones recommends that in addition to a careful X ray examination in doubtful

THE LANCET.

LONDON: SATURDAY, NOVEMBER 12, 1921.

Rural Medical Service in U.S.A.

IN this country we are certainly not sufficiently grateful to the rural practitioner, on whom the medical welfare of scattered populations in many shires is dependent. He has not within easy reach facilities for consultation with specialist physicians or surgeons, or for the hospital treatment of complicated cases; and the nursing on which he can call is still too often exiguous and defective. It is the resourcefulness and competence of a high proportion of rural practitioners which oft-times has averted calamity and safeguarded the health of rural communities. A great ideal of the Ministry of Health is to strengthen the position of the general practitioner by placing him in close organic relation with specialists in the various branches of medicine. We hope that this service is now in the making, though the difficulties which lie ahead are many and various.

There are two forces tending to modify the problem of rural medical attendance: the increasing facilities for easy travel of doctors and patients by road and train, and, on the other hand, the growing dislike of medical practitioners to settle in the remote rural districts where they are most urgently required. The rural practitioner has not available laboratory and consultant facilities, or hospital beds, or skilled nursing, for the large proportion of his patients for whom these are required. That provision of exactly these things formed a great part of the scheme outlined in the Dawson Report is well known; but for the time being the country doctor's disabilities in many directions remain. Much can be learnt from a comparison with American experience, which is one of greater difficulties and scantier and less efficient service than in this country; and a report printed in the October issue of the *American Journal of Public Health* of a Committee on Medical Service contains information directly to the point. The indicated problems have been studied especially in New York State, but the difficulties in other States are even more acute. In New York State there are 83 places containing a population varying from four or five hundred to several thousands which have applied to the State Department of Health to assist them in securing a physician. There are stated to be in the whole country thousands of communities, even in the most populous States, which are similarly situated. The reasons given for this rural lack of doctors in the United States include the physical hardships of rural practice, and the fact that doctors share the psychological trend of many men towards city life. A more potent reason is the realisation by recent medical graduates in the States of the complexity and difficulties of modern medical diagnosis and treatment; and in America as in this country, while it is agreed that consultative facilities must be made available in rural as in city practice, the question is being asked whether our medical schools are not tending to exaggerate the dependence of medical practice on various branches of laboratory work, and whether the powers of personal observation are failing to be educated in these schools. All reflections of this sort have to be carefully scrutinised—in the guise of common-sense they often advocate scientific retrogression. Specialists, some with most limited and unbalanced knowledge, are multiplying in the States, and it is becoming seriously difficult for the American public to obtain well-informed and skilful medical attendance in ordinary cases of illness. Here are the words of the report referred to above:—

> "In his passion for arriving at an exact diagnosis the modern physician too often *seems to overlook, or has not been taught to value, the little niceties of medical practice, the simple remedies, attention to details, however trivial, the personal touch which made the physician of a bygone day such a welcome visitor to the sick-room.*"

The menace of undue specialisation is regarded so seriously by this Committee as to lead them to ask the question whether the time has not arrived when, for the protection of the public and the good name of the medical profession, the licensing boards should require medical graduates to engage for a period of years in general practice before being permitted to take up a specialty, including that of general surgery, and then only after a minimum period of special study under stipulated conditions. This is a more reasonable proposition than the one which used to be put forward in this country to return to the old apprenticeship system, under which the student was supposed to learn how to conduct a practice while laying in some haphazard way the foundations of a scientific training. But each suggestion appears to regard the work of the laboratory as something separate from clinical work, while the whole spirit of modern education is to make of scientific training a living and growing whole. To institute special examinations would do little to prevent the chances of bad specialism; to restrain the recently qualified man from following his bent while inspired with keenness, and while in close touch with his educational centre and its facilities, would certainly not increase the chances of good specialism.

The public health department of the State of New York, of which Dr. HERMANN BIGGS is the Chief Commissioner, has boldly proposed by means of a State subsidy to place in all districts of the State where they are needed, and when consent to this is given by the county and city governments, the following provisions—viz., hospitals with adequate medical service, laboratories, nursing service, and occasional clinic and consultation services, provided by the State Department of Health. The Bills for initiating these services, called "Health Center Bills," have twice failed to pass the two legislatures of the State, largely owing to the opposition of the medical profession. That they will be further pressed is certain, as also that in some form or other this essential means of assisting rural medical practitioners in their arduous and difficult work will eventually be provided. It will be noted that the proposed service leaves the local service of private medical practice untouched, supplementing it by providing what otherwise would be almost entirely lacking.

◆

The Health of the School Children.[1]

IN the annual report of the Chief Medical Officer of the Board of Education we have been accustomed to find a detailed study of the defaults from the normal in the health of our school population, with valuable comments upon their causes and the preferable methods of their prevention. The document which appeared last week is as interesting as any of its predecessors, and no citizen, medical or lay, can read it without

---

[1] Annual Report of the Chief Medical Officer of the Board of Education, 1920. Published by His Majesty's Stationery Office. 1921. 6s.

But if the London hospitals are to earn this grant they must themselves raise a similar amount. In view, however, of the fact that a number of hospitals have already, or shortly will have, exhausted their realisable assets, the Commission have decided in certain cases to make emergency grants in anticipation of the new money which will have to be raised. The total amount of the present emergency grant is £77,900, which is to be distributed as follows:—

Canning Town	£700
East London Hospital for Children	3,000
Elizabeth Garrett Anderson Hospital for Women ..	600
Great Northern Central Hospital	11,000
Hampstead General Hospital	3,400
Hospital for Epilepsy	850
Hospital for Sick Children	4,000
Infants' Hospital	1,000
King's College Hospital	9,000
London Temperance Hospital	2,000
Metropolitan Hospital	750
Middlesex Hospital	3,000
Mildmay Mission Hospital	400
National Hospital for the Paralysed	800
Prince of Wales's General Hospital	2,200
Queen Charlotte's Lying-in Hospital	3,000
Queen Mary's Hospital for the East End	1,000
Queen's Hospital for Children	2,100
Royal Free Hospital	12,000
Royal National Orthopædic Hospital	3,000
Royal Waterloo Hospital for Women and Children ..	500
Samaritan Free Hospital for Women	800
South London Hospital for Women	800
University College Hospital	12,000

These grants are in no case more than half the amount of the estimated deficits for 1921; and the Commission have not felt justified at this stage in making emergency grants to any hospitals whose realisable assets exceed their liabilities, as such hospitals, not having exhausted their credit, are not compelled to close beds immediately, but can continue their activities at any rate for the present. It will, therefore, be understood that the receipt of a substantial grant does not mean that a hospital is relieved of the necessity of appealing to the generosity of the public. On the contrary, as the grant is in no case more than half the estimated deficit, it will be seen that those hospitals which receive the largest share are precisely those which are most in need of additional revenue.

A PORTABLE DISINFECTOR.

MEDICAL officers of health in general, but particularly those in districts of large area, small population, and slender purse, will welcome any new appliance providing efficient disinfection with increased mobility and diminished cost. In rural areas in particular the types of steam disinfector at present generally available are such as to render any general scheme of disinfection for the district difficult in application. Even those forms of disinfector which are mobile to the extent of moving on wheels are often not readily capable of negotiating the small by-roads leading to the more remote farms and cottages; while the cost of moving the apparatus, or in the alternative of carrying the infected articles to the apparatus, may at the present time be a material part of the cost of disinfection. Medical officers of health faced with this problem will do well to refer to an account[1] by Dr. F. E. Wynne, M.O.H. for Sheffield, of an adaptation for municipal work of the "sack steam disinfector" used during the war by the Egyptian Expeditionary Force. The apparatus is not described in that paper in sufficient detail to be readily understood by those not familiar with its prototype, while Dr. Wynne's light-hearted reference to its principle as the "ingenious utilisation of the lightness and latent heat of steam" may be somewhat tantalising to the uninformed. The results obtained by use of the apparatus, however, appear to be sufficiently extraordinary to invite careful consideration. In the first place, it is so light and readily packed that a light model can readily be carried on a pedal-bicycle, while a heavier model can be conveyed on the back-carrier of a motor-bicycle. Then its disinfecting capacity, in view of its size, appears to be phenomenal. It is stated to be capable of effectively disinfecting 1½ tons of textile in six hours; 120 single blankets in an hour; 150 lb. of underclothing in 15 minutes; or ten suits of outer clothing in five minutes. A single suit of clothing can be disinfected, dried, and put into use again within ten minutes. This extraordinarily active disinfecting capacity is produced at a very small expenditure of oil from an oil-stove. One pint of oil, costing *3d.* (now even less), lasts ten minutes. The cost of the oil for disinfecting one set of clothing would be *3d.*; 30 blankets, *7½d.*; a ton of textiles, *7s.*—these are the figures as given by Dr. Wynne. The capital cost of the whole apparatus is stated to be very small in comparison with that of the most modest of the ordinary steam disinfectors now in general use. It is clear that if this apparatus makes good—and the tenor of the article in question suggests that it can already be considered as having done so—then Dr. Wynne will be fully justified in referring to it as an invention revolutionising the practice of disinfection. We commend his article to the consideration of all concerned with the practical problems of disinfection.

A CASE OF DEATH AFTER VACCINATION.

A CASE of death following vaccination was before Dr. S. Ingleby Oddie, coroner for Westminster City and Liberty, on Oct. 28th. The deceased was a female child aged 4 months, daughter of a corporal in the R.A.M.C. She was vaccinated on Sept. 27th, at the Rochester Row Military Hospital, where the medical officer cleaned the skin thoroughly, smeared on Government vaccine, and scratched through it with a sterile needle. The vaccination was done on the leg and the place was protected by a shield. The child, however, kicked off the shield on the second day. The leg becoming troublesome, the child was taken daily to the Military Hospital, and on Oct. 11th was admitted to St. George's Hospital, where she died on Oct. 27th. The lymph came from the Government establishment and at least a dozen other children were vaccinated from the batch, no other case going wrong. A fresh tube was used for this child. The house surgeon at St. George's Hospital reported that on admission the child was suffering from cellulitis of the right leg, apparently originating from three vaccination wounds in the calf. The cellulitis steadily spread up the thigh and buttock and by the fourth day had assumed definite characteristics of erysipelas with a well-defined red edge to the inflammatory area. The inflammation spread to the other leg, the back, chest, abdomen, and arm. The patient's general condition was comparatively good until the 25th, when signs of toxæmia became more evident. There was a little diarrhœa on the 23rd. Anti-streptococcal serum was given, 70 c.cm. in all, along with stimulants and subcutaneous saline injections. The cause of death was stated to be toxæmia following erysipelas associated with a vaccination wound, and Dr. Oddie recorded a verdict to that effect, adding that the vaccination had been properly carried out and that death was due to misadventure.

REFLEX MECHANISM OF LUMBAGO AND SCIATICA.

THE theory that lumbago and certain other forms of backache, as well as such a closely allied condition as sciatica, are to be regarded as reflex neuralgias, like the trigeminal neuralgia due to dental caries, finds considerable support in recent investigations carried out by Dr. Folke Lindstedt[1] of Stockholm. He argues that if this group of diseases is to be regarded as the result of various reflexes, painful and otherwise, and not as strictly local phenomena, then they should be far more common in persons with a neurotic constitution and with morbid conditions of the bones and soft tissues, than in healthy persons. To put this including those also in which union does take place, but the zygote is incapable of full development. For it may perish, as Prof. ARTHUR ROBINSON has pointed out,[1] in the morula or blastula stage, or even *after it has become attached to the decidua,* when an abortion results. These faulty characteristics may be developmental in origin; they may even, according to Prof. ROBINSON's suggestive view, be a manifestation of the variations which occur normally in the reproductive process. On the other hand, they may be due to faulty parental metabolism, which in turn may depend on the absence of particular foodstuffs in the diet. The influence of diet on reproduction has long been known, especially as it concerns the lower forms of animal life. But relatively little has been done in the exploration of this influence in higher types. REYNOLDS and MACOMBER[2] have experimented on the influence of diet in causing sterility in a group of the mammalia—namely, rats. They constructed four "deficiency diets," the first being low in fat-soluble vitamin, the second low in proteins, the third low in salts, especially calcium; the fourth was low in all three, but had an excess of carbohydrates, and is called by the authors a "double-deficiency" or war diet. On a stock diet, 65 per cent. of the matings of these rats proved fertile; when they were fed on deficiency diets, which were given in unlimited quantity, the percentage of fertile matings fell to 55 when the deficiency was in fat-soluble vitamin, 31 when the deficiency was in calcium, and 14 when the deficiency was in proteins. The fertility of rats raised on these diets was also delayed. The fertilities of individual rats were ascertained by repeated matings, and some striking results were obtained, for it was found that the expectation of fertility of a given mating could be approximately ascertained by multiplying the individual fertilities. Thus two individuals with a calculated fertility of 0·8 each would yield a product of 0·64, which represents the standard fertility of these rats, as mentioned above; and the union of two such individuals would almost certainly be fertile. When the product of the fertilities falls below 0·45, the mating is infertile; thus, if a rat with a fertility of 0·8, were mated with one of 0·5 (product 0·40) the mating would be sterile. When the ovaries of rats on deficiency diets were examined microscopically, they showed no anatomical changes to distinguish them from the ovaries of normal animals, except those of rats fed on the double-deficiency diet, which did exhibit certain changes which the authors could not interpret. The American authors remark that "the work of ROBINSON on prenatal death makes it probable that certain ova contain within themselves conditions which make complete development impossible; but these conditions may or may not be morphologically visible." One further observation is noteworthy. Among rats fed on stock diet, macerated fœtuses appear to be unknown; at least the authors have been unable to find any mention of such in the literature. But in matings on the single-deficiency diets four such deliveries occurred, and there were two more in eight deliveries of young rats who had been reared on the war diet and were subsequently placed on ample diet and mated with normal rats.

[1] Acta. Med. Scand., 1921, vol. lv., Nr. 3.

REYNOLDS and MACOMBER properly point out that it is unsafe to reason from one species to another. But they cite some most instructive cases. In one a married couple had had no living children, each pregnancy resulting in miscarriage; a careful inquiry brought out the fact that the diet of the mother was obviously deficient in calcium, for after this was remedied, she produced a living child. In another case the husband had been a well-known sportsman, eating a large protein diet. He took up professional work and a sedentary life, and then married; one miscarriage was the only result. He went in for three months' athletic training, with only moderate intellectual work, and shortly after his wife conceived, and later was delivered at term. In a third case the normal assimilation of food by the wife was interfered with by an enormously over-loaded sigmoid. Attention to the bowels was followed by pregnancy and the delivery of a living child. In a fourth case the husband was thoroughly fertile but the wife had an anteflexion and an undeveloped cervix, with a cystic right ovary. She was treated by operation, but though dysmenorrhœa was relieved, and the general condition improved, no pregnancy followed. She was 20 pounds under the insurance weight, tired easily, and was pale and nervous. She was put on a regulated diet designed to increase weight, and under this regimen she gained 10 pounds in weight in two months. A year later she reported that she was six months pregnant, and she was subsequently delivered at term.

These results may mean only that the chances of fertility are improved when both parents are in good condition, but it would appear that there is anyhow room for further research along these lines. In consideration of cases of sterility, attention is too often limited to the anatomical and pathological conditions, whereas in some cases at least the physiological conditions may not be conducive to fertility.

◆

THE SCOPE OF UROLOGY

ACCEPTING the dictionary definition of urology—the sum of what is known regarding the urine—the specialty covers a very wide field of medicine; and in this sense it has long been construed by the American Urological Association, and by continental writers such as FRISCH and ZUCKERKANDL. A recent volume of transactions of the former contains articles on renal tuberculosis and on the specific gravity of the blood. The standard text-book by the latter includes an exhaustive section on the chemical examination of the urine. The Section of Urology of the Royal Society of Medicine was travelling in the same direction when it appointed a physician to fill the presidential chair this year; and Sir THOMAS HORDER, whose address we print in full at the front of this issue, after paying a tribute to the work of his predecessor, Sir PETER FREYER, expressed the hope that surgeons, physicians, bacteriologists, and biochemists should be numbered among the members of the Section. That was the desire of those to whose efforts the Section owed its being.

NATIONAL HEALTH INSURANCE: GOVERNMENT OF IRELAND ACT.—The National Health Insurance Joint Committee has appointed a committee, under the chairmanship of Sir Alfred Watson, K.C.B., the Government Actuary, *to consider the steps necessary to carry out the provisions* of the Government of Ireland Act in respect of National Health Insurance. The membership of the committee is as follows: Sir Alfred W. Watson, K.C.B., chairman; Mr. J. A. Dale, Permanent Secretary of the Ministry of Labour (Northern Ireland); Sir Joseph Glynn, chairman of the *National Health Insurance Commission* (Ireland); Mr. M. L. Gwyer, C.B., solicitor to the Ministry of Health; Sir Walter S. Kinnear, K.B.E., deputy chairman of the National Health Insurance Joint Committee; Mr. E. J. Strohmenger, C.B., financial adviser to the National Health *Insurance Joint Committee.* Inquiries should be addressed to the Secretary of the Committee, Mr. G. S. W. Epps, Government Actuary's Department, Buckingham Gate, London, S.W. 1.

[1] THE LANCET, May 14th, 1921.

[2] Jour. of Amer. Med. Assoc., July 16th, 1921.

tration of carbon monoxide in parts per 10,000 of air equals three, there is no perceptible physiological effect. When it equals six there is just a perceptible effect. When it equals nine headache and nausea are induced. When it equals 15 or more the conditions are dangerous to life.

INTRAVENOUS COPPER IN TUBERCLE.

MANY investigators, especially in Japan, have, in the treatment of human and animal tuberculosis, found advantage in using cyanides and copper salts, copper salts apparently stimulating the growth of fibrous tissue, while cyanides are better tolerated than other copper salts and do not coagulate albumin. In the *Annali di Medicina Navale* for August, Prof. E. Trocello, of the Royal Italian Navy, reports experiments he has made on the cure of tuberculosis in guinea-pigs by the intravenous injection of "cuprocian," a double cyanide of copper and potassium. Prof. Trocello inoculated guinea-pigs with virulent tubercle bacilli in the thigh, and, two or three weeks later, when it was clear that infection had occurred, he began to administer the salt. Its lethal dose is 3 milligrammes per kilo of guinea-pig: his curative dose was 1 or 2 mgm. per kilo every three or four days. Of eight animals, five died of general tuberculosis, three others survived four, seven, and seven and a half months. The weight of those which survived so long increased for a month or more after the injections (subcutaneous) were begun, and the ulcer or sinus which had formed at the seat of inoculation healed in two cases. No tubercle bacilli could be found after death in the bodies of these three, either by histological examination or by inoculation. The inguinal glands were always enlarged before the treatment was begun, and only in these glands could giant cells be found (nowhere else in the body), and even here there was no caseation. Tubercle formation was not observed in any other organ or tissue. There was greatly increased formation of fibrous tissue, particularly noticeable in the other lymph glands; and the spleen, which, in the tuberculosis of guinea-pigs, usually increased to two or three times the normal weight, was here reduced in size by a half and was cirrhosed and hard. Some small areas in the lungs that might have been taken for tubercles contained no lymphoid cells, but only epithelial cells with deeply staining nuclei and no caseation. These appearances are not due to the cuprocyanate itself but to its influence on the tuberculous infective process, whose noxa, the living tubercle bacillus, is killed, and the life of the infected guinea-pig is thereby prolonged. Prof. Trocello is proceeding with further researches on the precise meaning of these observations, in the hope of eliciting information of value in the treatment of tuberculosis in man.

RUDOLF VIRCHOW.

PROFESSORS of pathology are not in the list of professors of medicine and the allied sciences who are allowed by law to sign certificates under the Cruelty to Animals Act, 39 and 40 Vict. c. 77, for the exemption from its provisions of experiments made on living animals for the discovery of new knowledge. It is often supposed that their exclusion was due to a suspicion that they were too deeply involved and interested to be trusted; in fact, they were left out because in 1877 they did not exist. And now we are reminded that it is only 100 years since the father of modern pathology was born, and many will remember that it is but 19 years since that he died. It was Virchow's great achievement in biology to conceive—and his still greater achievement to convince the world—that the cells of the body are one thing and the intercellular substances another, that cells arise from cells and not from unorganised fluids, and that the processes of pathology are fundamentally cellular processes. It is difficult for us to grasp clearly what this must have meant, because we cannot really visualise a time when cells and lymph were thought to be interchangeable and when the histological arrangements of the body were not much clearer than the Yorkshireman's summary of the anatomy of slugs, "just moosh." The fertility of the Cellularpathologie has been of something like the same order as that of the Origin of Species, published a year later. The ideas of both have become so incorporated in our common daily thought that we are apt to forget that they were ever found out as something new. And if in recent years Virchow's concept of the body as a congeries of cells has to some extent receded, it has done so only by forming a sure foundation for a superstructure in which organs and organisms are the effective units rather than their component bricks. Virchow began to teach us how to understand the "body as a whole" by taking it to pieces; may the synthesis which is now reared on his analysis prove as well grounded and enduring.

STILLBIRTH, ITS PREVENTION.

THE importance of adequate antenatal supervision is now well recognised by all those concerned in the administration of large lying-in clinics. Unfortunately, the means available for carrying out such supervision are largely inadequate. Most of the accidents and toxæmias of pregnancy and childbirth can be prevented if only the pregnant woman is properly safeguarded during her pregnancy, and such care is even more important than that actually exercised at the time of her confinement. At the present day, when so much attention is being paid to the welfare of the new-born child, there is some danger of the even greater necessity for the care of the child before it is born being overlooked. Antenatal clinics are still few and far between, and it is probable that a very small percentage only of pregnant women consult their medical attendant before the birth of their child, and even when they do so, only too often no steps are taken to watch and supervise their health during the whole of this important period. In a well-conducted lying-in clinic every woman who applies for admission to the clinic for her confinement is seen and examined during her pregnancy, but even in these favourable circumstances many women will not attend as they ought, or only do so when they feel ill. Such neglect is the main cause not only of most of the accidents of childbirth, but even to a greater extent of the toxæmias of pregnancy and parturition with their attendant dangers. If we must confess that even in properly conducted clinics many women escape the care and attention which they should all receive during their pregnancy, how much greater is the failure in this respect in ordinary practice. In a paper which is published in the current issue of the *Edinburgh Medical Journal*, on stillbirth its causes and prevention, Dr. F. J. Browne has shown clearly that a very large percentage of stillbirths and neonatal deaths could be prevented by adequate antenatal supervision. Deaths, for example, from such causes as craniotomy, asphyxia, and cerebral hæmorrhage as a result of difficult breech and forceps deliveries are all preventable, and the conditions giving rise to them are readily recognisable by the medical attendant, if the patient is only properly examined before her confinement. It must be remembered that in many of these cases the fatal result is due to disproportion between the fœtus and the pelvic canal, and that the child is often particularly well nourished and before birth quite healthy; it is precisely the fact that the child is large and well developed that leads to the extra danger to its life. In the same way the recognition and treatment of syphilis, so potent a cause of stillbirth, is easily carried out if the patient comes under observation during her pregnancy, and the results that have been obtained show that healthy children may certainly be born if treatment is carried out on modern lines. The real danger to the child's life arises from the fact that only too often the women do not come under observation until the time of their delivery, when prevention is impossible and treatment is too late. To remedy this Dr. Browne pleads for the compulsory, or better, the voluntary notification of the pregnancy of every expectant mother. With cases of bone diseases, an exploratory incision should be made, and a frozen section examined at the time of the operation in order to determine the exact pathological process and to prevent unnecessary amputation. Treatment should consist in free incision of the periosteum and opening of the medullary canal.

QUALIFICATION AND COMPETENCY.

As will be seen by reference to our Parliamentary Report last week (p. 983) Sir Samuel Hoare asked the Home Secretary whether a wardress with no nursing experience had recently been placed in charge of the convicted hospital at Holloway over the heads of five trained nurses; whether this appointment was made on the advice of the Advisory Nursing Board; and the names of the personnel of that Board. To this question the Home Secretary truly replied that it was "not the case that a wardress with no nursing experience had been placed in charge of the convicted hospital at Holloway." He went on to say that the officer in question had had much nursing experience extending over a period of 17 years. He added the names of the Advisory Nursing Board, a strong body, but admitted that it had not been consulted. Probably what Sir Samuel Hoare meant to ask was whether the officer appointed was a trained and qualified nurse. The Home Secretary said: "She (the officer in question) is reported by the medical officers to be fully qualified and very capable." Had he been a doctor he would not have used the term "fully qualified," for that is generally understood as meaning that the individual in question has had full professional training and has been found qualified on examination, and not that he or she is competent. It may well be that in this case the officer is quite competent, but that does not necessarily mean that she has had full hospital training and has passed a qualifying examination. There are at Holloway five fully-trained nurses, and the hardship appears to be that an officer has been placed over them who, whatever her personal attainments may be, has not the guinea stamp conferred by examination after full training. What is the Advisory Nursing Board for, if it is not invited to advise?

LIVING SUTURES IN OPERATIVE SURGERY.

W. E. Gallie and A. B. LeMesurier have recently described[1] a most interesting series of experiments on the transplantation of fascia, aponeurosis, and tendon. The work on animals and the clinical operative procedures that have been developed have extended over a period of eight years and appear to be very conclusive. Repeating the earlier experiments of Lewis of Chicago, it was first shown that if a strip of fascia is excised completely and sewn back into position it continues to live, and after a short period of inflammatory œdema there is nothing to indicate histologically that cells or fibres are in any way changed, and their physiological value seems unaltered; this experiment gave the same result with muscle-aponeurosis and tendon, but in the tendon transplants the central part degenerated unless the transplants had been split longitudinally or freely incised to allow lymph to permeate. There is, however, no proliferation of the essential cells of the grafts, and if sutured in place by catgut they unite to their surroundings by ordinary scar tissue. The fibres of scar tissue are irregular and loosely arranged, and when subjected to strain show a constant tendency to stretch, so that the cut edges of the fascia separate widely; especially is this the case with tendon grafts. This fact explains the failure of many of the operations for cure of large herniæ by fixing fascial transplants by ordinary methods of suture, and for bridging gaps in tendons by similar means. Further experiments showed that this separation of the graft could be prevented by carefully scraping it free of all areolar tissue, scarifying it, and placing the graft in actual contact with its bed over a considerable distance by means of weaving the transplant into the edges of the gap to be filled. From this observation was developed the idea of using long strips of fascia threaded on large-eyed needles, thus converting the transplants into living sutures. The results of this method have been uniformly successful, provided the living suture at each point of puncture is firmly fixed by knotting, gaps in fascia being firmly closed by a trellis-work of living sutures and examined microscopically at intervals; at the end of six weeks the transplants were shown to be living and firm, and the condition was unchanged after 12 months, there being no widening of the gap that had been filled. The authors showed cases in sufficient numbers to prove conclusively the great clinical value of their experiments, the cases including a rupture of the ligamentum patellæ of a year's standing cured by a graft of the tendo Achillis sutured in position with the plantaris tendon, anchoring of the patella for lateral dislocation, suspension of the foot for paralytic foot-drop, closure of the gap in the capsule of the shoulder for recurrent dislocation, fixation of the trapezius to the humerus by fascial suture for deltoid paralysis, repair of injured tendons of the forearm, cure of congenital ptosis, and most important of all, the cure of 30 specially difficult cases of hernia. There were no failures; in herniæ no attempt was made to drag structures into abnormal positions, the gap being closed in each case by weaving sutures of fascia lata into the edges of the surrounding muscles and aponeuroses, stretching the living sutures across the gap just tightly enough to make them lie flat. A further paper[2] deals particularly with the implantation of tendons, and shows that wounds of tendons heal by ordinary scar tissue which, when subjected to strain, is liable to stretch or break unless it is present in considerable quantities; to unite tendon to bone it is necessary to remove all areolar membranes from the surface, and to place the tendon in contact with raw bone over a considerable distance, preferably after splitting the tendon to procure an extensive raw area; to unite tendon to tendon it is necessary to place raw surfaces in contact over a sufficient distance to ensure the required strength in the scar, and this may be done by splicing one tendon into the other. The work described has a wide practical application in large classes of cases difficult or impossible to treat with success by older methods, and it is likely therefore to prove of great value.

VOLUNTARY HOSPITALS COMMISSION: EMERGENCY GRANTS TO LONDON HOSPITALS.

THE King Edward's Hospital Fund, as the Local Voluntary Hospital Committee for London, have now reported to the Hospitals Commission in regard to the situation of the London hospitals. They estimate that the aggregate deficit on the maintenance account for the year ending Dec. 31st, 1921, will amount to at least £360,000. Commenting upon this situation, the Commission states: This is less than the corresponding figure for 1920, but the gravity of the situation is shown by the fact that without exception all the larger general hospitals, including all the medical schools, will show heavy deficits. Moreover, a number of hospitals have now exhausted all their realisable assets, and without immediate assistance will have no alternative but to close beds. It is a condition of the Government grant of £500,000, which has to meet the needs not of London only but of the whole of Great Britain, that a corresponding amount must be raised by the hospitals themselves. As the total deficits for the year were estimated by Lord Cave's Committee at £1,000,000, the importance of the pound for pound rule is manifest. The Hospitals Commission have provisionally appropriated £180,000 for London, which is half the total deficits for the year as estimated by the King's Fund.

[1] Canadian Medical Association Journal, July, 1921.

[2] American Journal of Surgery, September, 1921.

In healthy feet the higher the internal malleolus is naturally from the ground the easier it is for the internal malleolar group of muscles to do their work, getting as they do a straighter pull than when the malleolus is low down; and, conversely, the nearer it is to the ground the greater is the work required of these muscles. Artificially raised heels might, therefore, be expected to make the work easier, and this would doubtless be so were it not that the centre of gravity is thus thrown forwards, giving the muscles too much *constant* work. Even with a moderate—e.g., a three-quarter inch—heel a plumb line falls not opposite the sustentaculum tali, but opposite the head of the astragalus, throwing a constant strain upon the inferior calcaneo-clavicular ligament and the tendon of tibialis posticus; to relieve this strain the feet are usually instinctively splayed. Correct alignment is as necessary in a walking machine as in any other mechanism if one is to secure efficiency and durability, and the nearer the toes are kept to the middle line (the line of progression) the greater is the economy of power. When the habit of walking with splayed feet becomes established, propulsion in walking is done by the outer half of the gastrocnemius and by the peronei, dorsiflexion (if any) being effected by the extensors of the four smaller toes and the peroneus brevis and tertius. The tibiales and the flexors of the big toe then get practically no exercise and become relatively longer and weaker than the evertors, propulsion thus being effected by the muscles which raise the outer side of the foot and tend to flatten the arch. Teachers of dancing, gymnastics, and physical culture to this day almost invariably teach their pupils to stand with their feet splayed, quite oblivious of the evil effects. In the army also men are trained to stand "at ease" with the feet at an angle of 45°, the weight of their bodies and equipment being equally divided between their heels and toes—that is, resting on the arch. No wonder then that at least 90 per cent. of the temporary army were more or less flat-footed. The mere act of separating the big toes from each other tends to lower the arch of a weak foot, as the invertors of the foot are idle and the evertors in a favourable position for contracting. Also, the weight is thrown relatively further inward and forward on the arch than when the big toes are kept parallel. Abduction of the big toe from the other toes helps to raise the arch, but in most boots this is prevented by the snow-plough shape of the front of the boot pushing the big toe outwards. No appliance can cure hallux valgus whilst such boots are worn. Training, raised heels, and badly shaped toes of boots thus encourage men to stand with feet splayed and in course of time to walk in the same way, with the result that the muscles capable of making the arch strong and elastic are prevented or discouraged from acting effectively.

Strain Resulting from Wearing Heeled Boots.

A man wearing heeled boots stands on a slope, the gradient of which depends on the height of the boot heel and the length of the arch. If the body and legs were not furnished with joints he would resemble the tower of Pisa, but up till old age muscular action to some extent corrects the tilting, and enables strong persons to preserve a fairly erect carriage, the back muscles, and the extensors of thigh, leg, and foot unconsciously coming into action. When a soldier stands at "attention" all these muscles are in contraction to an extreme degree. The civilian is content with a milder effort, and although these muscles are contracted, there is a perceptible bending of the knees, the joint never being completely extended, and the capsule and lateral ligaments constantly stretched, accounting possibly for the frequent complaints of weak knees and easily displaced cartilages; there is a forward bending of the head; the lumbar curve is somewhat flattened; the feet generally splayed; and there is a slight stoop of the shoulders and a corresponding partial contraction of his chest. These faults disappear while exercising in a gymnasium, returning as soon as boots are resumed. The compensatory flexion of the knees is concealed by the clothing, but may be observed in the bare knees of schoolboys and of men wearing kilts, and in theatrical women wearing tights. The tibia is then inclined slightly forwards, and the leg cannot be maintained in this position without wasting neuro-muscular energy. The exhaustion and even pain caused by the continuous contraction of the calf muscles and peroneus longus when heeled boots are worn may be relieved by discarding boot heels, thus relaxing the muscles, the operation of excising part of the peroneus longus tendon being quite unnecessary. That white men's calf muscles are "muscle-bound" is shown by the fact that if a soldier's feet be examined when he is lying on his side his toes are invariably pointing downwards, the foot being at an obtuse angle to the leg, instead of at right angles as it would be if all the leg muscles were relaxed, and as it is seen in an infant. Gray and Cunningham both state that in the erect position the foot is at right angles to the leg. This, I contend, is the natural angle of the foot also when resting, the extension of the foot being caused by the tone of the calf muscles being greater than that of the dorsiflexors. Boot heels, by causing the calf muscles to be "muscle-bound," are responsible for the belief that extension is the normal position of the foot when at rest, the point being of some practical importance in fracture of the tibia, where the unrelaxed calf muscles tend to cause over-riding of the broken ends of the bone.

The average height of the heel of a man's boot is three-quarters of an inch, and this is sufficient to throw a man's head 9 in. off the vertical if he is 5 ft. 7 in. in height. If he weighs 11 stone, the weight required to pull him back to the vertical position is 56 lb. This may be verified roughly by using a log of wood of this height and weight with a base of the same width as the arch of the foot (6 in.), tilting it by a block three-quarters of an inch thick and attaching a rope and weight led over a pulley. A soldier has also his equipment (say 60 lb.) to support, in addition to the 56 lb. mentioned above, thus doubling the weight he is supposed to carry. No matter how he distributes the equipment around his body, he has to exert a constant effort to resist the 116 lb. pulling him downwards and forwards which would not be the case if his boots were heelless. This is doubtless one factor in the ætiology of soldier's heart, as even a healthy heart is not always equal to the strain. Indeed, without suggesting that boot heels cause all the troubles that flesh is heir to, it is quite possible that they are a factor in the causation of many conditions due to fatigue and nervous exhaustion. Much of the physical incapacity in persons over 50 years of age which is attributed to "old age," rheumatism, and sciatica arises from the strain on their musculature caused by the constant wearing of heeled boots.

It is obvious that the higher the heel the greater is the muscular effort necessary for the maintenance of the erect position. The head of a woman of 5 ft. 6 in. with an arch 6 in. wide is thrown 2 ft. off the perpendicular when she wears a 2 in. heel, thus entailing a great strain on the muscles of the back and necessitating the use of corsets. A person wearing very high heels becomes practically digitigrade, the weight being transmitted from the tibia vertically down the tarsus and metatarsus, falling not on the crown of the arch but vertically down the anterior pier. Although in this position there may appear to be quite a good arch, the feet are in many cases quite flat from weakness of the invertors and plantar flexors, and persons accustomed to the wearing of such heels are useless at long-distance walking, quick walking, or at any test of strength of the arch, such as leaping. The average woman gets no spring from the arch of the foot, being content with a lateral wobble of the ankle and rotation of the foot around its long axis instead of the natural springy heel-and-toe action. Any elasticity she gets is from flexion and extension at the knee, her feet being no more springy than blocks of wood. Using the knees in this way involves a much greater expenditure of energy than when the spring is derived from theory to the test of figures, he examined 1578 recruits, and he classified them according as they were perfectly healthy or subject to serious or slight morbid conditions. By "serious morbid conditions" he means practically every disease which may affect the lower half of the body, and his long list includes marked deformities of the spine, appendicitis, hernia, varicocele, traumatic and other diseases of the hip and knee, genu valgum, varum and recurvatum, severe flat-foot, hallux valgus, persistent or relapsing polyarthritis, varicose veins, and general static weakness. By "slight morbid conditions" he means similar but less serious divergences from the normal. He inquired of each recruit as to the occurrence, past or present, of sciatica, lumbago, and other forms of backache, and found that in 117 cases, or 7·4 per cent., the object of the inquiry had suffered from lumbago. But while this was the case in as high a proportion as 24·5 per cent. of the recruits in the category "serious morbid conditions," only 1·7 per cent. of the healthy recruits had suffered from lumbago. In other words, lumbago was 14 times more common among recruits suffering from one or more of the diseases referred to than in perfectly healthy recruits. The incidence of lumbago among recruits in the intermediate category suffering from minor ailments was 6·1 per cent. Similar figures were obtained in the case of sciatica, the incidence of which was as high as 3·46 per cent. in recruits subject to "a serious morbid condition," and only 0·12 per cent. in healthy recruits. Dr. Lindstedt is so impressed by the importance of this reflex mechanism in the provocation of lumbago that he suspects this mechanism to have played a part even in the 15 cases of lumbago found among healthy recruits. Their freedom from any morbid process capable of exciting a reflex lumbago was, he thinks, probably more apparent than real, and such a condition as spina bifida occulta is apt to be overlooked, although its capacity for exciting reflex disturbances cannot be ignored. If Dr. Lindstedt's conclusions are correct, a valuable clue to the successful treatment of lumbago and allied diseases is indicated, and in attempting to cure them the physician will extend his activities to comparatively distant parts of the body.

LIFE INSURANCE IN THE TROPICS.

At the first sessional meeting of the Royal Society of Tropical Medicine and Hygiene, which we briefly reported in our issue of Oct. 29th, Sir James Cantlie and others discussed the subject of life insurance in the tropics. It was pointed out that conditions of life in hot climates had recently greatly improved, that it was unjust in many cases for insurance companies to add a substantial percentage to the ordinary premiums simply because the party insuring resided within certain zones. That life in tropical and hitherto unhealthy countries has greatly improved both in comfort and freedom from risks is certain, and for this many factors are responsible. The most important, it would appear to us, is the greater knowledge of how the maladies peculiar to the warm countries are spread, an outcome of the advance in medical knowledge during the last quarter of a century. Apart from this, the motor-car and the electric fan exert an influence that it is hard to estimate in percentages, but is none the less real. A medical officer of a large town in India, who had some 20 years to his credit, once remarked that the hot weather had no terrors for him now as, thanks to the fan, he could always sleep at night and could go about in comfort in his car during the day. It is impossible for anybody who does not remember India in the pre-fan and pre-motor days fully to appreciate the force of this remark. As was pointed out by the speakers during the discussion, insurance companies are in the hands of their actuaries, and actuaries deal with figures, which are presumably founded on facts. Those responsible for fixing premiums have, in most cases, never been to the tropics and are not medical men. In the annual Government reports vital statistics affecting Europeans are necessarily brief and perfunctory; the native returns are more fully discussed and these reports are much too long as it is. Hence, owing to lack of exact data and the need of insurance companies to play for safety, an addition of 2, 3, or 5 per cent. is made to the ordinary premium, which in many instances is quite unjustifiable. Insurance companies who wish to deal fairly by the European resident abroad would do well to appoint expert advisers in tropical conditions, even if the numbers insured would hardly for the moment justify the expense incurred. American companies appear to be better informed as to health conditions in hot climates, and have a much more flexible system of working. During the discussion it came out that the first five years of the colonist's residence were still regarded as the danger period, Sir Leonard Rogers remarking that even this assumption was now largely untrue owing to the effect of antityphoid inoculation. Apart from the enteric fevers, the risk of death is not greater at this period than at any other. The European's power of resistance is never so high as when he has just left England.

MOTOR EXHAUST GAS IN CONFINED SPACES.

A report of considerable interest to the users of motor-cars appears in recent issues of the *Journal of Industrial Hygiene*, based upon an investigation made by Y. Henderson, H. W. Haggard, M. C. Teague, A. L. Prince, and R. M. Wunderlich, undertaken to determine the limits of safety of ventilation in the projected tunnel under the Hudson river between New York and Jersey City. The tunnel is to be 1100 yards long between ventilating shafts on the two sides of the river, and 2830 yards from portal to portal; it is to be used for motor traffic, and danger arises from carbon monoxide given off in exhaust gas. Exhaust gas contains on an average 6 per cent.—i.e., 600 parts per 10,000, of carbon monoxide. This gas is stated to be the only considerable toxic constituent from gasoline, but exhaust gas from coal distillate (benzol) contains accessory toxic substances. The problem of the research was to ascertain what percentage of carbon monoxide could be permitted for an exposure of 45 minutes, the maximum period likely to be occupied by the slowest vehicle in traversing the tunnel, a period during which no energetic exercise would be taken. Incidentally attention is drawn to the danger from which fatalities have resulted arising in small garages, or to a man crawling under a car when its engine is running, or when the engine of a car standing ahead is "idling." Under such conditions slight headaches are frequent, while severe headaches, nausea, and emotional disturbances up to hysterical mirth, anger, or grief, or even maniacal manifestations, are not very unusual. Several cases of severe poisoning from exhaust gas have been recorded [1] in our own columns. In the American investigation a large number of experiments, in which individuals were exposed in a chamber to atmospheres containing varying amounts of carbon monoxide, were carried out to determine the rates at which this gas, at different concentrations, is absorbed and subsequently eliminated. The results showed that after one hour's exposure at rest, the concentration of carbon monoxide in the blood reached approximately half what would be reached by indefinite exposure, but that by doubling the volume of breathing through exercise this concentration might be reached in half an hour. Elimination in fresh air was found to take place at the rate of 30 to 50 per cent. per hour. The conclusion is arrived at, for passengers with an exposure of 45 minutes in the tunnel, that complete safety and an assurance of freedom from disagreeable effects can be obtained if the carbon monoxide content does not exceed four parts per 10,000. General standards are also given. When the time in hours multiplied by the concen-

[1] THE LANCET, 1920, i., 1331.

On first dispensing with boot heels walking is not quite pleasant owing to the spastic or muscle-bound condition of the calf muscles and the relative weakness of tibialis anticus, but as the latter recovers tone and peroneus longus and the calf muscles relax, the muscular balance is gradually restored. (Fig. 4.) Soon the legs get straighter at the knees, the figure becomes more erect, the shoulders and head resume their natural position, the chest measurement gets larger and breathing easier, the back muscles get less spastic and the abdomen flatter, the foot gets shorter and more shapely from raising of the arch, the tendency to eversion disappears, walking becomes a pleasure, and health, strength, and stamina improve. Immediate good results from discarding heels should not, however, be expected, muscles which have been in more or less continuous contraction for years being, of course, incapable of relaxing the instant the strain is removed.

Nurses suffering from flat-foot are usually advised to abandon high heels, but changing to lower heels does them no good, what is required being no heels. A person wearing a heelless boot can tolerate a much thicker sole than he would in an ordinary boot, the movement in walking in the former being quite different from the modern artificial walk.

Remedies for Flat-foot.

Many of the remedies hitherto employed are useless, among them being (*a*) arch supports in heeled boots, which are usually either too strong to be flexible or not strong enough for the constant weight of the body; (*b*) raising the inner side of the sole and heel, which is only a palliative and not a cure; (*c*) standing tip-toe exercises and cycling, both of which are injurious as they develop the calf muscles and peronei longi which are invariably relatively too well-developed already, and do not sufficiently exercise tibialis anticus. In cycling, dorsiflexion of the ankle being done chiefly by the descent of the opposite pedal, tibialis anticus does not require to contract actively. Tip-toe exercises with the heels separated and big toes touching also fail, as abducting the heels is not equivalent to inverting completely the feet (abduction of the heels being done from the hip-joint), and rising on the toes in this position does not exercise the tibialis anticus, which is relaxed instead of contracted during the movement. In standing tip-toe exercises most of the work is done by the gastrocnemius and soleus, the other muscles of the leg unaided being incapable of raising the body to the tip-toe position as they act round corners (the malleoli). After the calf muscles have initiated the movement, the tendons passing under the malleoli come into play, and, when on tip-toe, help to preserve this posture. The exercise is unnecessary, as the same movement takes place in spurning the ground in walking, with the advantage in the latter case that during the contraction of the muscles of the propelling leg the weight is for the moment on the other foot. In heelless boots the movement starts from the ground, and the calf muscles have therefore a greater range of contraction, so that the tibialis posticus group have a longer time to get into action. Also in walking the flexor longus hallucis gets a chance of complete contraction, whereas in tip-toe exercise the sole of the big toe is on the ground and remains more extended than flexed.

What is required then is to exercise the arch supporters independently of the peronei and calf muscles, the three essential exercises in addition to correct walking as already described being (1) dorsiflexion, (2) plantar flexion, (3) inversion. Unless, however, boot heels are permanently discarded, perfect feet cannot be expected from these or any other exercises.

1. Dorsiflex the inverted foot, helping with hand if necessary, and getting someone to pull down the heel if the calf muscles cannot relax voluntarily.

2. Plantar flexion should be performed with the inverted foot (*a*) flexed and (*b*) extended, an attempt being made to close the foot like a fist. After thorough traction, relax all the plantar flexors completely, repeat contraction and relaxation alternately, concentrating the attention on the process. This exercise should be done with the foot in the extended position only when the patient has intelligence and power enough to keep the gastrocnemius and soleus relaxed.

3. Invert the foot completely, with foot extended and flexed respectively. Relax. Repeat.

Other useful exercises are: 4. Walking on the outer side of the feet and lifting each foot to cross the other at each step. 5. Lifting gradually increased weights with the inverted foot. 6. Circumduction of the foot from without inwards—i.e., invert, dorsiflex, extend. Relax always after each completed movement in every exercise. 7. Separate big toe from the others. Adduct it. Relax. Repeat. 8. Sitting on chair extend knees to the utmost, dorsiflexing the feet at the same time. Relax. Repeat. 9. Standing on heels and outer sides of feet, toes off the ground, lean back as far as possible. 10. Walking in boots the soles of which are thicker than the heels. Old boots with heels removed and soles thickened are useful for this exercise. Passive movements, massage, and electricity are all useful adjuncts, but none is essential. Where, however, adhesions or ankyloses exist, they should be broken down before starting treatment.

MEDICINE AND THE LAW.

The Legal Aspects of the Case of Harold Jones.

AT the Monmouthshire Assizes on Nov. 1st Harold Jones, a boy 15 years of age, pleaded guilty to the murder of a little girl named Florence Little at Abertillery on July 18th. The information given to Mr. Justice Roche before sentence was passed included the reading of two confessions by Harold Jones, one containing details of the killing of Florence Little, the other admitting the murder of another child, Freda Burnell, on Feb. 5th. Jones had been tried and acquitted of the murder of Freda Burnell, his defence having been publicly subscribed for, and he had been welcomed back to his home by applauding crowds of neighbours. To this the judge referred as having probably fostered the boy's vanity and made him more ready to commit his second crime. The case has many features of medical interest, while the details have appeared so recently in the press that they need no repetition. The plea of guilty followed by a sentence of detention during His Majesty's pleasure calls attention to Section 103 of the Children Act, 1908, which provides that "Sentence of death shall not be pronounced against a child" (under 14) "or young person" (between 14 and 16), but that he shall be sentenced as above and detained "in such place and under such conditions as the Secretary of State may direct and whilst so detained shall be deemed to be in legal custody." It is remarkable that the section makes no reference to the age of the young person at the time of the commission of his crime. Counsel for the defence alluded to this in urging the acceptance of the plea of guilty. His argument that Harold Jones might have had to be tried as an adult murderer, if through his pleading not guilty his trial had taken place next January, when he would have been 16 years of age, is liable to the comment that such postponement would hardly have been necessary, even if a later date had been fixed for the trial, owing to the defence not being ready. It points, however, to what is sufficiently obvious, that if Harold Jones had been brought to trial after his sixteenth birthday, it would have been the duty of those defending him to do what they could to prove an abnormal mental condition affecting him, and to obtain a verdict of "guilty but insane." It is almost equally clear that this defence could not have succeeded under the rules of law governing such verdicts. A boy of 15 who has killed in close succession two young girls must be regarded by most people as suffering from "disease of the mind." There was, in addition, a statement that in one of his pockets seven women's handkerchiefs were found, an indication pointing to a sexual element this view we substantially agree if it is necessary to safeguard the health of the child from its birth up to and during its school age; it is equally important to ensure that it shall not be handicapped at birth or even lose its life for want of proper supervision of its mother during her pregnancy. Child welfare centres are undoubtedly doing a very good work, but their utility would be increased, and a large number of lives of new-born infants would be saved, if proper antenatal centres were established in close association with them all over the country, and if some means were devised, such as the notification of pregnancy, to ensure that no expectant mother should lack careful supervision and treatment during the whole of her pregnancy.

THE BRUSSELS MEDICAL DEGREE.

FOR the last 40 years the University of Brussels has granted an M.D. degree to those already holding British and Colonial medical diplomas. For this degree, which did not entitle its possessor to practise medicine in Belgium, no course of study or residence was required, and only a single examination in final medical subjects, largely of an oral nature, was demanded. The degree was popular in the eighties and nineties with those who, for one reason or another, were on the British Medical Register without obtaining a university degree in medicine. This examination, in abeyance during the war, was formally discontinued after the armistice under the circumstances narrated in THE LANCET of July 23rd by Dr. Arthur Haydon as Hon. Sec. of the Brussels Medical Graduates' Association. Dr. Haydon now sends us for publication a copy of a letter received by him from the Foreign Office.

Foreign Office, S.W. 1, 10th October, 1921.

SIR,—With reference to the letter from this Department No. W7278/4161/4 of the 9th of July last, I am directed by the Marquess Curzon of Kedleston to inform you that His Majesty's Ambassador at Brussels has received a note from the Minister for Foreign Affairs stating that no privilege has been withdrawn from British and Colonial students who have obtained a degree of M.D. at the Free University of Brussels.

As regards the future, the University authorities have decided, in order to promote the relations of the University with foreign countries, that all foreign students should be called upon to fulfil the same regulations; and that they therefore cannot concede special privileges to British and Colonial students.

The latter may still enter their names at the University under the conditions laid down on page 13 of the *Réglement Organique* and on page 2 of the *Réglement pour la Collation des Grades Scientifiques*, both of which documents are enclosed herewith.—I am, Sir, your obedient servant,

R. H. CAMPBELL.

Quite apart from the granting of this Brussels M.D. to foreigners, owing to the special circumstances of the war reciprocity was set up in 1915 between Belgium and this country whereby, under Part II. of the Medical Act, 1886, Belgian medical graduates were entitled to a place in the foreign section of the British Medical Register, and 60 or more Belgian medical graduates actually availed themselves of this privilege. Similarly, an English medical graduate became entitled to practise medicine in Belgium without other formality than registration. As was pointed out in the Students' Number of THE LANCET, this reciprocity came to an end in December, 1920, and from the wording of the letter cited above it appears that the holders of British medical diplomas will no longer be entitled to any preferential treatment in regard to Belgian medical qualification or registration.

THE next session of the General Council of Medical Education and Registration will commence at 2 P.M., on Tuesday, Nov. 22nd, when Sir Donald MacAlister, the President, will take the chair.

Sir George Joseph Hamilton Evatt, K.C.B., who founded the R.A.M.C. Volunteers in conjunction with Sir James Cantlie, and who had done much for reform and efficiency in the medical organisation of the army, died in London on Nov. 5th, aged 77.

MODERN FOOTWEAR AS A CAUSE OF FATIGUE, MUSCULAR RHEUMATISM, AND FLAT-FOOT.

WITH NOTES ON AN IMPROVED TYPE OF BOOT.

BY S. D. FAIRWEATHER, M.B., CH.B. ABERD.

THE arch of the normal human foot may be compared to the semi-elliptical spring employed in motor-chassis construction; the body-weight, however, does not rest constantly upon the crown of the arch or spring, but is thrown on it only when the resistance of the arch is required to deaden any jar or shock thrown on the foot. The arch, which rests on three points, the heel, the ball of the foot, and the fifth metatarsal bone, is supported by the plantar ligaments and fascia, assisted by the ligamentous action of the various muscles—tibiales anticus and posticus, the long and short flexors of the toes, abductor hallucis, and the small muscles of the sole of the foot. Of these muscles, tibialis anticus acts on the whole arch from above, lifting it as one lifts a bunch of keys by a ring, ensuring that the antero-posterior arch will act in the proper plane, and preventing rotation of the arch around its long axis. The peroneus longus braces up the transverse arch diagonally, but if unopposed by a properly developed tibialis anticus it tends to pull down the antero-posterior arch. Flat-foot accompanied by spasm of the peroneus longus corroborates this point.

The *spring* of the human foot does not depend so much on the curvature and thickness of the arch as on the quality (strength, contractibility, and relaxability) of the muscles which support it, just as the efficiency of a metal spring depends not on the curvature and section alone, but on its flexibility and strength. While, however, the height of the arch is no true criterion of efficiency—otherwise pes cavus would be the ideal foot—and a long foot with a comparatively low arch *may* be quite efficient, the ideal arch should be fairly high in order to obviate the necessity for the excessive contraction of the supporting muscles, which must take place before they can resist any strain thrown upon the foot, and which is unnecessary if the muscles and tendons are of the proper length. The height of the arch should be measured from the head of the astragalus to the ground whilst the subject is standing erect on one foot. A great muscular development under the arch partly fills up the concavity and makes the bony framework appear lower than it really is. The present method of testing for flat-foot—i.e., asking the patient to stand on tip-toe—is no criterion of the efficiency of the arch except in cases in which the bones are ankylosed. Most of the work of rising on tip-toe is done by the gastrocnemius and soleus, the tibialis posticus and peroneus longus helping the calf muscles to maintain this posture. The efficiency of the arch can best be gauged by marking the tubercle of the scaphoid while the subject stands on one foot, the tubercle being then allowed to sink as near the ground as possible and then elevated by contracting the tibiales and all the plantar flexors. Measuring the distance the scaphoid has moved and multiplying by the weight of the person will give the efficiency of the arch.

Modern Footwear.

In a normal barefooted white man the body-weight when standing falls opposite the heel—i.e., on the posterior pier of the arch which is more vertical, more rigid, and shorter than the anterior—and not on the crown of the arch; the balance of the body being so perfect that only a minimum of effort is required to keep erect. When the heels are raised even a quarter of an inch from the ground the centre of gravity is thrown forward, the plumb-line falling opposite the crown of the arch or even farther forward, according to the height of the heel from the ground. (Figs. 1 and 2.)

of the Conseil Départemental d'Hygiène. He suggests that medical school inspectors should be appointed for a period of six years and should still be allowed to devote most of their time to private practice. As so far no definite scale of remuneration has been established, he proposes to standardise the annual salary at Fr.1500 which, under the present system, corresponds approximately to the average sum offered. Another proposal made at a recent congress—the "Congrès d'Hygiène Scolaire de Langue Française"—was that the post should be held by medical officers of health at a salary of Fr.15,000, who would act as school medical officers under the supervision of the Ministry of Health and would be debarred from private practice. According to this last scheme a school medical officer would be in charge of approximately eight of the circumscriptions of Dr. Gilbert Laurent's scheme. Amongst other reforms suggested is the establishment of more open-air classes; at present there are only three in Paris. It has also been urged that the school medical officer should be compelled to get in touch with the parents when a child shows signs of any morbid condition, such as anæmia, enlarged glands or tonsils, adenoids, ringworm, dental caries, &c., and give advice as to which hospital or dispensary the children should be taken for treatment; so far this is the custom only of certain individual school medical inspectors. On the whole, it would seem that there are also strong reasons in favour of revising the present system of medical inspection of schools in France.

Antivenereal Prophylaxis.

There seems to be at the moment a revival of interest in the antivenereal prophylactic measures by means of a calomel ointment first formulated over here by Dr. Roux, director of the Pasteur Institute of Paris, and also strongly recommended by Metchnikoff, when the latter was subdirector of the same Institute. Dr. A Gaudncheau has recently reported to the Société de Médecine Publique the results obtained after adding cyanide of mercury and thymol to the formula of MM. Roux and Metchnikoff. He mentioned that 68 men of the crew of a French cruiser were supplied with tubes of the ointment as prescribed by Dr. Gaudncheau and were told to apply it to the external genital organs, including the fossa navicularis, before sexual intercourse. In the course of a six months' voyage, during which the cruiser put in at several ports where venereal diseases are most prevalent, none of these 68 men contracted syphilis or gonorrhœa. Dr. Gaudncheau pointed out that of 181 men who only applied the ointment after sexual intercourses, five were contaminated; he also recalled previously reported statistics of 624 cases in which the ointment was applied before intercourse without a single failure of its effect. Convinced as he was of the value of such prophylaxis, he could only deplore the campaign waged against such measures by those who from a moral point of view objected to the procedure, preferring to use venereal diseases as a scarecrow. These views were warmly seconded by the President of the Society, Dr. E. Marchoux, of the Pasteur Institute, and by Dr. P. Boudin. Dr. Gaudncheau, in collaboration with Mr. P. Levaditi, of the Pasteur Institute of Paris, has also carried out a series of experiments, in which the value of calomel, cyanide of mercury, and thymol ointment was satisfactorily controlled by a series of tests in vitro, and by successful applications at the site of inoculation in the case of rabbits an hour after the insertion of the syphilitic virus. These experiments, as well as Dr. Gaudncheau's formula and the method of preparation of the corresponding ointment, have recently been described in a review[1] published under the scientific direction of Mr. A. Calmette, subdirector of the Pasteur Institute, and of Mr. Léon Bernard, professor of hygiene at the Faculté de Médecine de Paris.

Correspondence.

"Audi alteram partem."

THE EDUCATIONAL TREATMENT OF RESIDUAL HEARING IN DEAF CHILDREN.

To the Editor of THE LANCET.

SIR,—Teachers of the deaf are naturally interested in every effort made to improve the condition of the children they teach. Generally speaking, all that medical skill can do to prevent or improve deafness has been tried and exhausted before the children come under the teachers' care, so that deafness, whatever its degree, is almost always a settled condition in the children of our schools. Deafness, however, in children is rarely absolute. The large majority are capable of audible impression to some extent or other, and it is almost certain that between 30 and 40 per cent. of the pupils now in our schools have some power of hearing the voice, more or less loudly produced. The schools accept the duty of enlisting into the service of the individual child whatever advantage, however small, he may possess in the way of natural faculty, but there is a minimum below which for practical purposes it becomes valueless in his training. That minimum is reached at the point of appreciating the more audibly apparent vowel sounds. There are two main hopes that arise from the exercise of even this small degree of vowel hearing. The first is the improvement of the voice and speech of the child, and the other, the possibility, which is extremely remote, of the increase of the hearing power itself. Every teacher is aware of the favourable effects of even vowel hearing on the speech of deaf children, and every teacher would welcome any discovery that would lead to the improvement of the actual power of hearing in his pupils.

Dr. James Kerr Love, the well-known aurist of Glasgow, recently wrote in a note to the parents of deaf children:—

> "If your child has been born deaf, or if illness has caused deafness and loss of speech, his hearing will never return. The exceptions to this statement are so few that they are not worth considering in thinking of the future of your child."

My own experience of 34 years in schools for the deaf entirely confirms Dr. Love's statement. I have never known a single deaf child in schools to recover hearing power. It is very easy for either the teacher or the doctor to be completely misled into attributing to improved hearing power that which actually belongs to lip or speech reading. Excluding this, there is a further possibility of erroneous assumption in the matter from mistaking psychic phenomena for improvement in hearing. Each one of these vowel-hearing children hears an indefinite blur of sound which conveys no meaning to him, although it may be sufficient to enable him mechanically to produce some or other of the stronger vowel elements, and, as I have already said, with marked effect on the quality of voice and speech. Constant repetition of these realised sounds gives them a definite character, and they are more readily appreciated by the ear. Those sounds are united in simple words such as "father" (AR—ER), "good boy" (OO—OY), and even into simple sentences, as "What's your name?" (O—AW—AY), "How old are you?" (OW—O—AR—OO). The child hears only the vowel sounds and becomes used to their particular sequence and distance in specially practised forms, as above, associates the full form generally acquired by lip-reading or writing, and therefore gives the idea of increased hearing power, whereas, actually there is no real improvement at all in this direction, but only an improved recognition and association in the action of the arch of the foot, and the movement produces a much less graceful effect as the muscles employed are larger and less capable of fine movements.

---

[1] Revue d'Hygiène et de Police Sanitaire, October, 1921, tome xliii., No. 10.

It is noteworthy that an exceptional proportion of the prize-winners in jumping competitions at Highland games are tailors, the reason being that these men when at work sit in a squatting position with the feet well inverted. In spite of indoor life and lack of exercise the average tailor is more agile than other men, as the arch is spared the work of supporting his weight all day, and his muscles, being idle, remain elastic. *Sedentary people in general—e.g., clerks and students—are more agile than men who stand much, such as policemen and tram-drivers.*

FIG. 1.

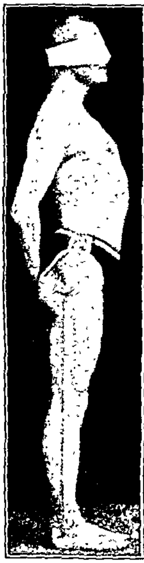

FIG. 2.

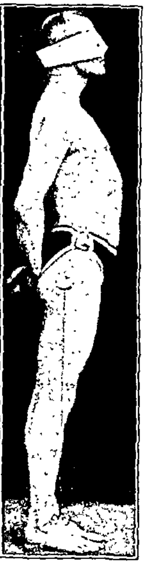

FIG. 1.—The muscles are equally relaxed and a *minimum of energy is required to stand erect with* the heels on the ground. The photograph was taken after wearing heelless boots for two years. The foot *is quite altered in shape, the heel not projecting* behind the leg as it formerly did. The plumb-line *falls from a point vertically below the centre of* gravity—*i.e.*, the last lumbar vertebra, as nearly as could be judged.

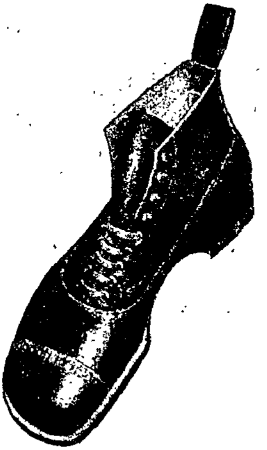
FIG. 2.—The back muscles, quadriceps, glutei, and calf *muscles are contracted by conscious effort to retain* the erect posture; even then the latter is not so good as in Fig. 1. The weight of the body is thrown on the spring ligament and internal malleolar group of muscles, to relieve which, when these muscles are weak or tired, people separate their feet in front. They then tend to walk with the feet everted, and the peronei do more of the work in walking than they should: there is thus a dragging down of the arch. Moreover, the tibialis anticus is elongated and weakened.

*The Heelless Boot.**

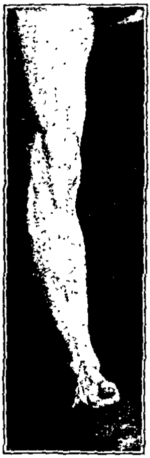
To prevent and cure flat-foot and the other evil effects of heels, *the boots should be so constructed* that the metatarso-phalangeal joint of the big toe, *all the toes, the outer side of the sole, and the heel shall rest on one place parallel to the ground.* Under the arch of the foot the sole should be curved with the convexity upwards and should be fairly flexible. The leather sole, which could be reinforced by spring steel from the heel to the ball of the big toe, should conform to the natural shape of the foot, and the heel and sole must be of the same thickness. The inner edge of the boot should be straight, as in American boots. Ample room should be allowed for flexion of the toes. The arching of the sole is not essential to cure flat-foot, but it looks better and allows the boot to be laced more firmly, thus *compensating for the* loss of muscular sense that *occurs in a foot* when any sort of footwear is used. Lacing the ordinary boot tightly pulls down the crown of the arch towards the flat sole which, being rigid, cannot fit into the arch. *The ideal boot as described is practically a* close-fitting, pliable *covering of leather, supporting without immobilising or hampering* the structures in the arch and ankle, the waist of the boot acting like an artificial annular ligament, bracing up the strained fascia and ligaments under the arch. (Fig. 3.)

FIG. 3.



"Heelless boot," showing heel and sole of same thickness, arched sole, and no curling up of toe.

FIG. 4.



To show development of tibialis anticus. When heels are worn this muscle is rarely as well developed as the calf muscles and peronei.

With heelless boots the carriage is erect and easy, and the improvement in balance is very marked when turning round, golfing, *waltzing, &c. It is noticeable* that footwear used for boxing, wrestling, tennis, athletics, and gymnastics, all of which exercises call *for a maximum of strength, speed, and accuracy of* footwork, is generally made with little or no heel. Owing to the os calcis resuming its natural relation to the ground, the calf muscles have a greater range of contraction, and this is shown by increase of power in high jumping and walking uphill. There is also a greater sense of firmness in the knees and ankles when standing, as also greater agility and quickness of foot work. In walking the feet should be kept parallel and a gliding movement of legs and feet adopted, the "steam-hammer" method of putting the feet to the ground being abandoned. The knee should scarcely be flexed and must not be raised, each foot being dorsiflexed in passing the other. Walking from the hip-joint and ankle should be cultivated, knee-joint action being *only slightly required in correct walking.*

---

* Very satisfactory boots and shoes of this type are supplied by Messrs. James Lorimer and Son, Aberdeen.

Association expects to receive early in 1922 a report embodying all the results of treatment up to that date), though some data are necessarily incomplete, there appears every prospect of these figures entirely justifying the claim that this serum method is giving better results than any other in use up to the present, especially when cases of trypanosomiasis *from the same countries* are compared.

The opinion, based on a clinical observation that "although the administration of one dose of salvarsan, neosalvarsan, or atoxyl is sufficient to sterilise the blood stream, symptoms reappear within a variable period averaging about four months and the disease progresses to a fatal termination" comes in for adverse criticism, although in the main it corresponds with the results revealed by an analysis of the figures put forward by Prof. Yorke and certainly agrees with the results of animal experiments detailed by Colonel Wenyon in his article in the *British Medical Journal* of Nov. 5th, wherein he states, "in experimentally inoculated small animals, such as mice, it is usually possible, by means of a single dose of a drug, to bring about the disappearance of trypanosomes from the peripheral blood, but almost invariably relapses occur in a comparatively short time and the animals die of the infection."

Finally, the Tropical Disease Prevention Association is not prejudiced in favour of any one method of treatment, but it does consider that fair play should be given to any method which has shown promise of success. This attitude is not conspicuous in Prof. Yorke's review. On the other hand, far from condemning the value of "Bayer 205," in spite of the fact that to the best of its knowledge this secret remedy has been used on only one human patient, the Association is, the more readily after Colonel Wenyon's experiments, prepared to investigate its importance. A German expedition under the auspices of our Colonial Office is now on its way to Rhodesia to test this treatment with the aid of our medical officers in the colony. The expedition, which I am assured by the Colonial Office is disinterested, is financed entirely by German commercial firms who, in view of the present value of the mark and the non-existence of German colonial interests, may or may not be disinterested also. Further, I am informed that the composition of "Bayer 205" will be revealed later. Past experience of German descriptions of the method of manufacture of "606" leads one to anticipate that this revelation may not enable others to reproduce the remedy in question.

It is, perhaps, not fully recognised by tropical experts working at home that treatment of such a disease as sleeping sickness must be administratively and economically practicable on a large scale as well as scientifically effective in a hospital at home. It cannot be stated too emphatically that the object of the Association is to try serum *and* other methods in the field in order to gauge their respective values for stamping out sleeping sickness.

I am, Sir, yours faithfully,

E. T. Jensen,

Hon. Secretary, Tropical Disease Prevention Association.

Harley-street, W., Nov. 7th, 1921.

BELLADONNA POISONING:

AN OVERDOSE OF ATROPINE.

To the Editor of The Lancet.

Sir,—In connexion with several cases of belladonna poisoning reported lately the following note may be of interest.

A boy of 19, of not a very high intellectual standard, on being discharged from hospital was given a prescription containing some citrate of potash. This prescription he ignored, and did not even take to the dispensary, but he abstracted from my consulting room a small 2 oz. glass stoppered bottle containing about an ounce of the "B.P." solution of atropine sulphate. This he took home with him, and about 2.30 P.M. took, on an empty stomach, a teaspoonful of the solution. Fortunately he did not take a tablespoonful, as he had been ordered to take of the citrate of potash mixture. About 4 P.M. he felt "queer" and his panel doctor was sent for, who gave him an emetic, and about 8.30 P.M. he was sent to the hospital, where I saw him on admission. He was restless and delirious, trying to get off the stretcher, though he could not stand. His pupils were widely dilated, and his mouth and throat very dry, but at no time was there noticed any scarlatiniform rash. A note from his doctor explained the circumstances of the case. No further emetic was given, but morphia (gr. ¼) and nitrate of pilocarpine (gr. ½) were injected, the urine drawn off to prevent any reabsorption, and 2 or 3 pints of strong hot coffee administered. At 11 he was no worse—a smaller dose of morphia and pilocarpine was administered—the urine again drawn off and more hot coffee given. At midnight he recognised the night sister and myself, and at 8 A.M. the next morning he was practically all right—the pupils were, however, still dilated. At noon he ate the usual hospital dinner, and the next day he was discharged.

I obtained the actual teaspoon used to measure the dose: "brimming full" it contains 90 minims, ordinarily "full" about 60 to 70 minims, so that with 1 gr. in 110 minims he must have taken at least ½ gr., and possibly more, of sulphate of atropia on an empty stomach.

I am, Sir, yours faithfully,

H. Neville Taylor, M.A. Camb., M.D. Dub., F.R.C.S. Edin.,

Surgeon, Ebbw Vale Hospital; Consulting Medical Officer, Ebbw Vale Medical Society.

Ebbw Vale, Nov. 1st, 1921.

OCCIPITO-POSTERIOR PRESENTATIONS.

To the Editor of The Lancet.

Sir,—May I call attention to a feature of modern obstetrics? It appears to me that persistent occipito-posterior presentations are not only commoner than text-books would lead us to believe, but tend yearly to become more frequent. In a recent British Medical Association lecture,[1] Prof. W. Blair Bell said that, "Owing to the fact that this presentation, if left alone, almost invariably rotates into the occipito-anterior position, the frequency of the occipito-posterior position as a primary presentation has probably been much underestimated." My experience does not teach me that "almost invariably" patience will resolve the awkward presentation into something simpler. Rather am I impressed by the multiplicity of cases in which labour proceeds until the persistence of this presentation leads to exhaustion of the maternal resources and constitutes a menace to mother and infant. Conversation with fellow practitioners and maternity nurses strengthens my conviction that such cases are on the increase. From rough notes of cases within my own limited experience, I find that in the year 1909 (out of 116 full-time labours attended) 8 were persistent occipito-posterior presentations; in 1918 (of 163) 22; in 1919 (of 115) 24; and in 1920 (of 126) 31. Reduced to percentages, these figures work out as 6·8 in 1909, and 13·1, 20·8, and 24·6 respectively for the last three years.

For various reasons I do not pause to discuss what evolutionary processes contribute to bring about this development. But I see that, if its reality be conceded, it is time that those who instruct potential obstetricians were agreed upon the method best calculated to meet this contingency in labour. Because, in a majority of cases, delay or faulty manipulation means damage to maternal structures—and the tale of injury may not end there. Quarter of a century ago, as a student, I heard of the method which I still deem best—application of forceps, rotation of the fœtal head, and traction—but my professor never himself practised the trick, and, indeed, towards the end of his life showed pride in that fact. Such an attitude, or at best a little bending, is still widely prevalent. Yet the manœuvre is simplicity itself. Chloroform anæsthesia is desirable but not imperative for its performance. Essential to success are (*a*) correct diagnosis of the "lie" of the head and accurate adjustment of the forceps; (*b*) secure maintenance of the "lock" until deliverance of the head, or its deposition within manual control in his abnormality. Before, however, a person indicted for murder can be found to have been insane at the time of the action it must be proved that at that time he was "labouring under such a defect of reason from disease of the mind as not to know the nature and quality of the act he was doing, or if he did know it, that he did not know he was doing what was wrong." Whatever modifications of what is known as the rule in McNaughton's case may have been at times suggested by the summing up of judges, or brought about by the verdicts of juries, they have been slight, and the law stands as stated above. If it were to be applied to the case of Harold Jones, it would be difficult to contend that a man or boy did not know the nature and quality of his act, who killed his victim as he did, or that he did not know that it was wrong when he concealed the body and washed away the bloodstains with careful cunning. It seems, therefore, that a verdict of guilty of murder followed by sentence of death would have been inevitable if, owing to the later incidence of an assize, he had passed his sixteenth birthday when brought to trial. It is almost inconceivable, however, that a lad of such an age, even with such a record, would have been hanged. His candid and callous confession of two murders would have told both ways. It would have been taken into account as evidence of defective mentality. The usual form of petitions in his favour would have been gone through, invoking the mercy of the Crown. The Home Secretary would have advised a reprieve, and after his sentence had been formally commuted for one of penal servitude, and after further consideration by the medical advisers of the Home Office, Harold Jones in all probability would have found himself in approximately the same situation that he now occupies. It would, however, have been a lengthy and clumsy process; but failure of the defence of insanity in the assize court would have called attention once again to the rule in McNaughton's case and to the law under which judges direct juries. If Jones had been convicted, reprieved, and eventually dealt with as a person suffering from a defect of reason, it would have added weight to the arguments of those, many of whom are distinguished members of the medical profession, who assert that the rule in McNaughton's case does not meet modern requirements. These are of the opinion that there are some persons who know the nature and quality of a criminal act and know that it is wrong, but to treat whom as responsible criminals, punishable as such, is neither reasonable nor humane.

---

[1] Delivered before the Bradford Division, May, 1921.

An Inquest without Post-mortem Examination.

At Chester County Court recently his Honour Judge Parsons was called on to decide whether a blacksmith had died as the result of an accident and in the course of his employment, so as to entitle his widow to an award under the Workmen's Compensation Act. The man had fallen dead on July 1st of this year after putting a tyre on a wheel; he had never complained of ill-health and was stated never to have received medical attention during his life. A medical man, who was called as a witness in the county court, was summoned after death had taken place, and as the result of what he then saw was of the opinion that the cause of death was syncope accelerated by the strain of laborious work and the extreme heat. There had been no post-mortem examination. The case for the employers in these circumstances was naturally that there was no evidence of any unusual strain or of anything amounting to an accident to account for the death of a blacksmith doing his usual work. Dr. William Lees, called on their behalf, gave an opinion, from what had been reported to him, that the deceased was suffering from high blood pressure due to thickened arteries and a dilated heart, but he pointed out with emphasis that as there had been no post-mortem examination it was not possible for anyone to state the cause of death with certainty. He could say what was the likely cause of death, but "most coroners' inquests were valueless because post mortems were refused to the doctor, especially in Chester." His Honour made an award in favour of the employers, having no evidence to support any other finding, and expressed himself as inclined to the opinion that a serious injustice might thereby be done, because no post-mortem examination had been held. He hoped that those directly or indirectly responsible for the conduct of coroners' inquests in that district would bear in mind the grave importance of post-mortem examination where the cause of death was not obvious from surface indications, and where serious interests might be involved. The public, and particularly the citizens of Chester, should be grateful to Dr. Lees for calling attention to this serious matter and to the county court judge for adding the weight of his authority to the representation made to him. The coroner's duty is to inquire and certify regarding a sudden death of which the cause is unknown; and there are few such cases, if any, in which a right conclusion can be arrived at with certainty without post-mortem examination. Certainty is important in all cases for the sake of accurate statistics in the interest of the public health, but doubly so where an issue may arise as to the right of survivors to compensation. A majority of the jury may require a coroner to order a post-mortem examination, but probably few jurors are aware of their power in this respect, or sufficiently alive to its importance to exercise it spontaneously.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Medical Inspection of Schools.

IN both medical and political circles here there is a growing movement in favour of the reorganisation of the system of medical inspection of schools. At present school medical officers are recruited by competitive examinations amongst practitioners who in due time express their wish to be admitted as candidates to the competition: "Concours pour le Recrutement de Médecins-inspecteurs des Écoles," which is held in various counties when there are vacancies. Under the present system candidates must be over 32 years of age, of French nationality, and must have been registered under the French Medical Act for at least five years. In the first part of the competition candidates are given two hours to write two papers, one in answer to a question on a children's disease, the other to one on hygiene in schools. A certain number of the candidates, in this instance 175, are selected and admitted to the second part of the examination which consists in the medical inspection of a school and in the oral answer to a question on school hygiene. School medical inspectors carry out their duties for a period of three years. These duties consist in giving at least one consultation a week in each school; the medical inspector has to meet the parents of any new scholar in order to fill in a card on which any morbid condition should be noted, and should also see the parents of any child who has been away from school for more than three days. No treatment is given at the schools, and private practice is permitted to school medical inspectors.

Various suggestions have been made concerning the reorganisation of this system, and it is probable that the Bill dealing with the revision of the French Medical Act, February, 1902, will incorporate some of the modifications which have been suggested. One criticism that has been made is that the number of school children to be under the superintendence of any one inspector has not been officially determined. Dr. Gilbert Laurent makes a suggestion, which carries the approval of the Commission of Hygiene of the Chamber, that this number should be limited to from 500 to 1000, each group forming a "circonscription." He also asked that the school medical inspector of every group should be selected from practitioners in the corresponding district by an election committee at Great Malvern, in the same year taking the degree of M.D. Brux. with honours. For 30 years Dr. Brockatt practised at Malvern, his strong personality, sound judgment, and exceptional medical skill causing his services to be sought after over a wide area in Worcester, Hereford, and adjoining counties. Much of his time and thought was given to the welfare of the boys at Malvern College, where he was medical officer for 18 years. His rule was to be informed of every case of illness or injury, however trivial it might seem to be, and the observance of this regulation did much to prevent the outbreak of epidemics in the school. He took much interest in Freemasonry, and was a past Master of the Malvern Lodge. He was also one of the founders of the Cheseldon Lodge attached to St. Thomas's Hospital. On retiring from practice he was presented by his old patients with a silver cup and a substantial cheque. Dr. Brockatt, who was unmarried, died after a long and painful illness borne with much fortitude.

EDGAR BEAUMONT, M.D. Durh.

Dr. Edgar Beaumont was born in 1860, and was the son of Josiah Beaumont, of Huddersfield. Entering the medical school of St. George's Hospital in 1881, and having previously begun his medical study in Yorkshire, he qualified M.R.C.S. in 1883 and L.R.C.P. and L.S.A. in the following year. In 1907 he took the M.D. at Durham. After a hard struggle in his early years he built up a good general practice in the neighbourhood of the Crystal Palace. His ability and happy disposition brought him success, for he had in a high degree the gift of becoming the friend as well as the medical guide of his patients. He touched life at many points; as surgeon to the Norwood Cottage Hospital he kept well abreast of modern developments and never spared himself. He was a keen horseman and sportsman and enjoyed his holidays like a boy. Some 20 years ago he collaborated, under the pseudonym of Clifford Halifax, with the late Mrs. L. T. Meade in a series of detective stories which appeared in the *Strand Magazine* and had a medical flavour, the investigator having a busy practice in Harley-street. The plots were mainly supplied by Beaumont, who, though urged to continue the series, never found time to do so.

A large number of St. George's men, as well as many patients and friends, will learn of Beaumont's death with sincere sorrow. He was highly popular for the excellent reasons that he was a good, generous, and charitable man, as well as a very competent practitioner. His health had long been unsatisfactory, and he had had several short attacks of acute illness since 1914. He was, however, spared the trials of a prolonged invalidism and incapacity for the life and work he loved, for he died in Charing Cross Hospital 12 hours after the onset of cerebral hæmorrhage. He leaves a widow and a married daughter.

DAVID DRYBROUGH GOLD, M.D.Edin.,
M.O.H. FOR HEREFORDSHIRE.

Dr. D. D. Gold died very suddenly at his residence, Rydal Mount, Hereford, on Friday, Nov. 4th, on returning from a performance at the Kemble theatre. He was found lying dead on the floor of his bedroom, and at the inquest, held on Saturday night, evidence was given that Dr. Gold had recently remarked to a medical friend that he suffered from pains in the chest, but he had not received medical treatment. To his wife and friends he appeared in his usual health, and had spent a very active week. A verdict of death from heart disease was recorded by the coroner, who sat without a jury.

Dr. Gold, who graduated M.B., C.M.Edin. in 1896 and obtained his M.D. in 1901, was formerly assistant M.O.H. for the county of Essex. A Scotsman by birth, he was nearly 50 years of age; in 1918 he married Mrs. Margaret Ward, youngest daughter of the late Mr. James Duffas, of Cupar, Fife. He had held the office of County M.O.H. for Herefordshire ever since January, 1909, and he was deservedly popular with all who came in contact with him. He took a prominent part in the work of the County Insurance Committee and, during the war, in Red Cross work. The news of his death was heard with great regret in the city and county of Hereford.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surgn. Comdr. E. T. P. Eames is placed on the retd. list at his own request, with rank of Surgn. Capt.

ARMY MEDICAL SERVICE.

Maj. and Bt. Lt.-Col. R. B. Ainsworth, R.A.M.C., to be Dep. Asst. Dir.-Gen., and to relinquish the temp. rank of Lt.-Col.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. and Bt.-Col. E. E. Powell is placed on ret. pay, and is granted the rank of Col.

Maj. and Bt. Lt.-Col. G. F. Sheehan is placed on the h.p. list on account of ill-health.

Maj. J. M. Cuthbert retires on ret. pay.

Lt. (temp. Capt.) M. C. Paterson to be Capt.

Temp. Lt. J. W. H. Steil to be temp. Capt.

J. D. Leahy to be temp. Lt.

The undermentioned temp Capts. relinquish their commns. and retain the rank of Capt.: G. D. K. Waldron, D. Finlayson, and A. A. Watson.

ARMY DENTAL CORPS.

Temp. Capt. C. V. Walker, Dental Surg., from Spec. List, to be Lt., and to be temp. Capt.

Lt. (temp. Capt.) L. S. Woodiwis to be Capt.

ARMY RESERVE OF OFFICERS.

Capt. H. W. Vaughan-Williams, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

The undermentioned officers, having attained the age limit, are retired and retain their rank, with permission to wear the prescribed uniform: Lt.-Cols. J. H. G. Whiteford, A. C. Miller, D. Durran, and A. Butler. Majs. G. S. Ward, J. N. Macmullan, and W. Dyson.

Capt. (now Maj.) H. W. Read is restored to the estbt.

Maj. F. Philip resigns his commn. and retains the rank of Maj., with permission to wear the prescribed uniform.

Capts. B. T. J. Glover, J. M. Johnstone, and J. S. Ranson resign their commns. and retain the rank of Capt.

Capt. A. S. Hooper, having attained the age limit, is retired and retains the rank of Capt.

1st S. Genl. Hosp.—Lt.-Col. (Bt.-Col.) F. Marsh, having attained the age limit, is retired and retains his rank.

4th Lond. Genl. Hosp.—Capt. H. S. Pendlebury, having attained the age limit, is retired and retains the rank of Capt.

TERRITORIAL ARMY RESERVE.

Maj. T. D. Laird, having attained the age limit, is retired and retains the rank of Maj., with permission to wear the prescribed uniform.

ROYAL AIR FORCE.

Flight-Lt. A. F. Wright relinquishes his temporary commn. on ceasing to be employed.

J. R. Crolius is granted a short service commn. as a Flight-Lt.

DEATHS IN THE SERVICES.

Major-General Sir George Joseph Hamilton Evatt, K.C.B., A.M.S. (retd.), died in London on Nov. 5th, aged 77. Educated at the Royal College of Surgeons and Trinity College, Dublin, he entered the army in 1866 and ten years later served in India with Sir H. Ross. He afterwards served in the Afghan War of 1878-80, and in the second campaign commanded a field hospital and took part in the advance to Kabul under Sir Charles Gough. He also served in the Suakin Expedition. He had held the posts of medical officer at the Royal Military Academy, Woolwich, sanitary officer at the Garrison, secretary to the Royal Victoria Hospital, Netley, and surgeon-general to the Second Army Corps at Salisbury. He was co-founder with Sir James Cantlie of the R.A.M.C. Volunteers in 1883. During the war he was president of the travelling medical board in the Western Command. We hope to publish a fuller notice of Sir George Evatt's career in an early issue of The Lancet.

known words and sentences of those elements of speech he has already indefinitely heard. These sounds, therefore, become mnemonics, calling up words and sentences acquired by means other than hearing for the unvoiced or semi-voiced sounds are not heard. No other conclusion is possible for the consonantal elements of speech generally make insufficient audible appeal to be recognised by actual hearing in these extremely hard of hearing cases. Moreover, if this were not so, apart from any psychic question whatever, there should be no difficulty in inducing children of this description to mechanically reproduce any word they "hear." I have tested cases of this sort by substituting such words as "rather" and "lather" for the known word, "father," and found them reproduced as the latter—a clear evidence that it was not actual hearing power, but rather the association and sequence of the heard vowels, a mnemonic phonetic memory, that accounted for the wrong reproduction. Unless, therefore, "results" in these cases are carefully analysed and traced to their source, even the very elect, whether teachers or doctors, may easily be deceived. And this frequently happens.

Over 30 years since I had charge of a class formed entirely of children with varying degrees of hearing, and 18 months' experience of this class, using the voice unaided or assisted as necessary by the double speaking tube, led me to the conviction that actual hearing power was in no way improved, but rather that the appreciation of what had been already heard was made greater—a qualitative rather than a quantitative improvement. Experience with cases of this nature continuously during the past 30 years entirely confirms my earlier judgment. Teachers do not exclude any scientific possibility, but they do say that these frequent promises for the physical relief of deafness, promises which they have never seen to materialise in any real amelioration of the condition of the deafness of children in our schools, unsettle the minds of parents of deaf children, and prevent them, in many cases, from giving such children the only hope they have—namely, suitable training and education. There is evidence, too, that medical men, including aurists, do not properly appreciate the extreme remoteness of restoring a serviceable degree of hearing power such as would make the child independent of visual means of understanding, and that the best place for such children is one which would not only conserve existing hearing power, but further carry on their oral and general education. In many cases parents and medical men do not understand the present condition of schools for the deaf. There is no doubt that many associate such schools with an atmosphere of perpetual silence, whereas in actual truth the modern school for the deaf is vocally noisier than the school for hearing children often is.

The attitude of teachers of the deaf towards this question is perfectly clear. They would welcome with open arms anything that would give to their pupils even a serviceable modicum of hearing ability, but so far as present knowledge is concerned they know that for the training of residual hearing power in deaf children, whether for increased appreciation or "sorting out" of already hazily heard speech or for the very remote possibility of developing existing hearing power, their methods, based as they are upon a scientific study of phonetics and the practical knowledge of the physical and psychic conditions of the deaf child, promise more effectually than anything yet known the fullest amelioration of the lot of the deaf. Teachers of the deaf have for many years advocated the scientific classification of deaf children according to the history and degree of deafness and their mental condition. If this were done it would be to the great advantage of the different types, but in present circumstances, and even when classification is achieved, teachers of the deaf claim that their special knowledge and experience mark them as more qualified than any other class of teacher or trainer for those children who suffer from deafness, whether complete or partial.

I am, Sir, yours faithfully,
A. J. STORY,
Chairman of the National College of
Stoke-on-Trent, Nov. 4th. Teachers of the Deaf.

To the Editor of THE LANCET.

SIR,—In Dr. Arthur F. Hurst's letter in your issue of Oct. 22nd he appears to claim that in any case of deaf-mutism, in which the vestibular reactions are normal, the deafness is functional. It would be interesting to know if Dr. Hurst is aware of the numerous cases now on record in which microscopic examinations of the labyrinths of deaf-mutes have shown a perfectly normal vestibular apparatus (including the cristæ of the semicircular canals, the macula of the utricle, with their associated nerves and ganglia), but a more or less completely degenerated cochlear apparatus. In the majority of cases the saccule was also affected. Functional examination of these patients showed a normal vestibular response. Some of them were completely deaf, while others showed remains of hearing, and it is these hearing remnants which Prof. Urbantschitsch was anxious to utilise by means of his harmonica and acoustic exercises.

For many years otologists have been in the habit of advising the parents of deaf-mutes with slight remains of hearing to speak to their children in a loud voice and to give the children noisy toys to play with. Dr. Hurst's patient efforts to educate these extremely deaf children are to be commended, but his assumption that the deafness is functional can hardly be accepted. Had the deafness been entirely of this nature, one would have expected sudden and complete restoration of hearing. Further, it is extremely difficult, if not impossible, to believe in a functional disorder of hearing arising in infancy.

I am, Sir, yours faithfully,
J. S. FRASER, M.B., F.R.C.S. Edin.
Edinburgh, Nov. 1st, 1921.

TRYPANOCIDE.

To the Editor of THE LANCET.

SIR,—With reference to the annotation on the Treatment of Sleeping Sickness, which appeared under this heading in your issue of Nov. 5th, I should like to correct a misapprehension in the last paragraph under which apparently Prof. Warrington Yorke laboured when he published his recent critical review in a medium which precluded the possibility of a reply.

The expressed object of the mission as endorsed by the Colonial Office is to test out and compare various methods of treatment already in vogue, or which may be put forward in the near future (the new German preparation "Bayer 205" having been specified) and further to place the Commission under the general direction of an independent scientist. As clinical and laboratory experience is a necessity, the Association has approached Prof. J. W. H. Eyre, of Guy's Hospital, who was in 1906 chairman of the working party of the Malta Fever Committee and he has signified his willingness to accept the post of director.

With reference to Prof. Yorke's criticism as to absence of controls I would point out that the work done by Marshall and Vassallo has been performed by them as Uganda medical officers in the field and in their spare time, without the great advantage of having their patients constantly in hospital and completely under their control, so that they have been unable to carry out all the controls and examinations which would have been possible in a well-equipped laboratory attached to a hospital in England. Further, they have carried out a method of treatment which they have found highly successful in practice and have offered several theories to explain these results. Taking their actual results as compared with other methods of treatment (the Tropical Disease Prevention

Public Health Services.

Scarlet Fever and Diphtheria in London.

A report presented on Nov. 5th to the Metropolitan Asylums Board by its Infectious Hospitals Committee, in considering the special measures required for dealing with the present abnormal seasonal rise of infectious disease, adds: "It is thought that the necessity for these special measures will only last for a few weeks." The report, which is dated Oct. 27th, runs as follows:—

The minimum number of patients in the Board's fever hospitals during 1921 was 5123 at midnight on Sept. 3rd. This *minimum* exceeds the *maximum* number of cases under treatment on any one day in 17 of the last 22 years. From Sept. 4th, when the present seasonal rise began, to midnight on Oct. 24th, 9501 fever cases were admitted and the number under treatment increased between those dates by 3586—viz., from 5123 to 9009. The latter number is 1530 more than on the corresponding date last year, and 340 more than the maximum number of patients under treatment on any one day last year (8669 on Nov. 23rd, 1920), when the seasonal rise was the highest in the Board's history. Since Sept. 3rd the daily admissions of fever cases have exceeded 200 on 21 occasions, the maximum having been 271 on Oct. 4th. The highest on any one day in previous years was 244 on Nov. 5th, 1920.

It may be taken that the Board have beds for about 9500 cases in all—i.e., approximately 900 more than the highest number under treatment last year. At the beginning of the week ended Oct. 22nd the acute hospitals were almost full, practically the whole of the beds then vacant being at the Southern and Orchard Hospitals, Dartford, and not available for direct admissions, but only for cases transferred, as soon as they become convalescent, from the acute hospitals, and it appeared unlikely, having regard to the altogether unprecedented rate at which applications for admission were being received, that the Board would be able to admit all the cases.

In these circumstances, in company with the deputy clerk to the Board and Dr. Caiger, medical superintendent of the South Western Hospital (acting in connexion with infectious fevers in place of the principal medical officer), our chairman saw Sir George Newman, K.C.B., chief medical officer of the Ministry of Health, on Oct. 18th, and discussed the position with him, and as a result a conference took place on Oct. 21st between the representatives of the Board appointed last year and of the medical officers of health—at which the Ministry of Health were also represented—and the following proposals were agreed to—viz.:

(i.) *Scarlet Fever.*—(*a*) On and from Tuesday, Oct. 25th, all applications for the admission of cases of scarlet fever to the Board's hospitals to be made, in the first instance, to the medical officer of health, who will select the most necessitous cases and advise the Board thereon. (*b*) Preference in admitting cases to be given to the poorer and more crowded districts, especially to cases coming from homes where there is unemployment.

(ii.) *Diphtheria.*—It is anticipated that there will be no delay in admitting all cases of diphtheria.

A supplementary statement issued by Mr. W. Eickhoff, chairman of the Infectious Hospitals Committee, brings the figures up to date, Nov. 4th:—

Number in hospital, Nov. 3rd, 1921	9146	Scarlet fever	6239
		Diphtheria	2901
Number a year ago	8041	Scarlet fever	5245
		Diphtheria	2363
Maximum last year, Nov. 23rd, 1920	8669	Scarlet fever	5664
		Diphtheria	2594

	Excess over this time last year.	Excess over maximum last year.
Scarlet fever	994	575
Diphtheria	538	307
All diseases	1105	777

From Sept. 4th to midnight on Nov. 3rd, 1921, 11,545 fever cases were admitted.

The number under treatment between midnight on Sept. 3rd and midnight on Nov. 3rd rose by 4023.

The report concludes by stating that a certain proportion of the patients now admitted show little or no clinical signs of the disease, but are merely bacteriological cases. It was agreed that the medical officers of health should impress upon the medical practitioners in their districts the great desirability of not making application for the admission to hospital of such cases.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Mental Treatment of Ex-Service Men.

Some confusion seems to have arisen as to the allowances payable by the Ministry of Pensions to ex-Service men undergoing treatment for mental disorder. In reply to a question in the House of Commons, Mr. Macpherson explained that men suffering from certifiable insanity due to war service were eligible for treatment and allowances at the expense of the Ministry in any institution approved by the Board of Control, which, in the opinion of his medical advisers, afforded the most appropriate treatment. Treatment allowances in respect of these patients were made on substantially the same basis as in other cases of in-patient treatment and did not vary with the institution. The officers, whose mental condition was due to service, at present in Chartfield were receiving maximum retired pay, but after consultation with the Board of Control the Ministry had not placed this home on the approved list for the reception of such patients and had refused to accept responsibility for the charges made there for medical treatment. This decision is in accordance with the general policy of the Ministry of Pensions, which is to separate persons suffering from certifiable insanity from other patients. Mr. Macpherson pointed out that he was bound to send certified patients to a place approved by the Board of Control. Chartfield had now been inspected and a report of the work done at this institution would be impartially considered when it was received.

HOUSE OF COMMONS.

Wednesday, Nov. 2nd.

National Health Insurance Bill.

The House went into Committee on the National Health Insurance (Prolongation of Insurance) Bill, Mr. James Hope in the chair.

Sir A. Mond (Minister of Health), answering questions with regard to the Bill, said that the additional benefits which would be paid under the measure would be paid by the approved societies. It was difficult to state exactly what those amounts would be, but there was every reason to believe that the figure might be taken as being between £500,000 and £750,000. The approved societies had, he said, a surplus of £5,000,000. In addition, every society had got a contingency fund, and in that there was no less than £2,000,000. Those societies who had a deficiency on valuation could fall back upon this £2,000,000. Therefore he thought they need not be alarmed in regard to finance. As to what benefits the people would receive who were going, so to speak, to have the extra contributions paid for them, obviously it was not proposed to pay the entire full benefit which was to be paid to those who had not fallen into arrears. It was proposed to pay (*a*) medical benefit to June, 1923; (*b*) full maternity benefit; (*c*) full additional benefit; (*d*) sickness benefit of 8*s.* for men and 7*s.* 6*d.* for women, compared with the full benefit. If the Bill was not passed very large numbers of people would fall out, and the whole National Insurance scheme would become endangered.

The Committee stage having been concluded, the Bill was considered on report.

On the motion for the third reading,

Sir G. Collins asked the Minister if he did not think that the time had arrived when all the Insurance Acts should be consolidated into one Act, and when there should be an inquiry into the whole working of National Insurance. He was aware that the Minister had held out hope that he might set up a Committee or Royal Commission to inquire into the working of the Act. He hoped that before the Bill passed its Third Reading, in view of the pressing need for economy in all matters, they might have some assurance from the Minister on that point.

Sir A. Mond agreed that a Consolidation Bill to consolidate all previous legislation on this subject would undoubtedly be of considerable value. Such a Bill was practically prepared, and it was a question only of finding Parliamentary time. He hoped that they would be able to pass such a Bill next session. He had been giving considerable attention to the matter of setting up some form of inquiry into the working of the National Health Insurance. He thought those who wished for an inquiry would be well advised not to press for it immediately, but to allow a more normal state of things to come about in which they could see more clearly where they were, and then to appoint an important commission to deal not merely with one aspect of the cost of administration but with a number of other aspects of the working of the scheme now brought forward.

The Bill was read a third time and passed.

upon the perineum, has been effected; *(c)* a gentle thrusting of head in instrument towards the uterine cavity to secure a sense of freedom before rotation is attempted; *(d)* the simple mechanical revolution of instrument with head as one turns a key to open a door; and *(e)* traction in the routine way, without any other preparation, once the occipito-anterior position has been attained.

Most authorities who commend the method consider that, when rotation has been managed, the forceps should be withdrawn and reapplied in the orthodox position (in conformity with the vaginal curve) but in practice neither embarrassment nor difficulty attends delivery without this precautionary manœuvre. Contrary to expectation, the instrument does not slip or prove awkward. And, always, the minimum of manipulation consistent with efficiency should be our ideal.

An objection raised by Dr. Robert Jardine before the Glasgow Obstetrical Society in March last, that "rotation of the head by forceps . . . . twisted the head on the neck while the shoulders are not turned," is theoretical only. The method offers no practical difficulties; but constitutes, in my experience, the readiest, safest, speediest solution of what is nowadays a common problem in obstetrics.

I am, Sir, yours faithfully,

Belfast, Oct. 31st, 1921. ROBERT WATSON.

BRITISH SPA FEDERATION.

To the Editor of THE LANCET.

SIR,—At the biennial meeting of this Federation, held recently, it was decided that for the future the British spas in the Federation—i.e., Bath, Buxton, Cheltenham, Droitwich, Harrogate, Leamington, Llandrindod Wells, and Woodhall—will require their patients to have medical prescriptions of not more than 12 months old for all treatments except a few generally recognised to be obtainable at any "hydro" or treatment establishment.

I am, Sir, yours faithfully,

F. J. C. BROOME,
Hon. Secretary.

Nov. 2nd, 1921.

⁂ The dangers of self-drugging are largely removed by any regulations which prevent the use of old prescriptions; these are often used by others than those for whom they were intended originally.—ED. L.

PEOPLE'S LEAGUE OF HEALTH.—Under the patronage of Her Majesty the Queen, a ball will take place at Devonshire House (lent by the owners, Messrs. Holland and Hannen and Cubitts) on Friday, Nov. 25th, in aid of the League. At the first issue ball tickets are priced at £2 2s.; they may be obtained, and boxes booked, at the box offices, from the members of the Ball and Fête Committee, and from G. Sherwood Foster, 7, Hanover-square, W. 1.

MEMORIAL TO LIEUT.-COL. E. F. HARRISON.—On Nov. 2nd, the Secretary of State for War unveiled the memorial erected in the Examination Hall of the Pharmaceutical Society, 17, Bloomsbury-square, in honour of the late Lieut.-Colonel E. F. Harrison, Controller of Chemical Warfare, and one of the most distinguished graduates of the Society's school. Colonel Harrison, it may be recalled, joined the army as a private in 1915, when he was 47 years of age. He was transferred as a corporal to the Special Anti-Gas Branch of the Royal Engineers after the first German gas offensive, and at once became identified as the leading spirit in the department organised to fight the menace of poison-gas warfare. He was closely associated with the evolution of the small box respirator, the most perfect of all anti-gas appliances, 20 million of which were manufactured before the end of the war. As a scientific pharmacist, Harrison had made a great reputation for himself before the war, and on his death, in November, 1918, from pneumonia probably aggravated by the effects of the gases to which he was exposed during his researches, his confrères organised a fund to perpetuate his memory. The memorial consists of an alabaster tablet, inlaid with mosaic, in which is set a circular bronze relief portrait. A biographical notice of Colonel Harrison by Prof. E. H. Starling appeared in THE LANCET, 1918, ii., 681.

Obituary.

JOHN WICKHAM LEGG, F.R.C.P. LOND., M.D. LOND., F.S.A.

Dr. J. Wickham Legg died at his home in Oxford on Oct. 28th at the age of 78. Although his chief work lay outside medicine he was at one time a notable figure in London medical circles. He qualified M.R.C.S. Eng. in 1866, becoming M.D. Lond. in 1868, M.R.C.P. Lond. in 1869, and F.R.C.P. Lond. in 1876. Soon after qualification Dr. Legg was chosen by Queen Victoria to act as tutor and medical attendant to her delicate son, Prince Leopold, Duke of Albany, and he continued to act in the latter capacity throughout the life of the prince. Dr. Legg became assistant physician to St. Bartholomew's Hospital in 1878; he remained on the staff for only nine years, retiring owing to ill-health in 1887. He was specially interested in the cardio-vascular system, published a treatise on Hæmophilia, and gave the Bradshaw lecture in 1883 on Cardiac Aneurysms. For the last 30 years of his life Dr. Legg devoted himself to archæological research in general and especially to the study of ancient documents relating to the churches, and was generally accepted as a liturgical expert. Dr. Legg's wife predeceased him; his only son is fellow and tutor of New College, Oxford.

Dr. Arthur Maude writes:—

I knew Wickham Legg well, and was his clinical assistant in the skin department at St. Bartholomew's. It was a pleasure which I can well recall to dine with him at his charming little house in Green-street. He was an excellent host, appreciated his own good fare, and was an interesting and stimulating talker and raconteur. Dr. Legg was appointed casualty physician in January, 1870, on the first institution of that office. He succeeded Dr. Norman Moore as demonstrator of morbid anatomy and was made lecturer on pathology in 1879. Legg was a very handsome man, always well dressed; he had undemocratic prejudices, and occasionally caused amusement among the students by airing them, but those who knew Legg knew their signification. He was a poor lecturer and seemed incapable of arranging a consecutive discourse, but he was a good clinical teacher and could illuminate his ideas with valuable medical anecdotes culled from history and from bygone medical writers. He was, moreover, a careful observer and a humble student when dealing with a subject new to him. Legg succeeded Mr. Morant Baker as dermatologist at Bart.'s, a difficult position since Baker was one of the best skin specialists in London at that time and Legg knew little about the subject when he got his appointment—a very usual position in all medical schools at that date. But he soon learned his subject. I was his first clinical assistant and we worked most agreeably together for six months in 1882, in a large and interesting clinique. In 1880 I saw a great deal of him in Dr. Gee's wards where I was then clerking, when he became the assistant physician corresponding to Dr. Gee. I owe much to his careful and learned instruction, especially in diseases of the liver and pancreas, a branch of pathology in which he took an interest secondary only to his interest in cardiology. He was even then a fine historian and had seen a good deal of British diplomacy abroad, being especially intimate with Sir Augustus Paget, when he was Minister at the Quirinal. I remember that in his library at Green-street he would take down book after book of eighteenth century memoirs to illustrate his wide knowledge of the intrigues of the bygone century.

Though Wickham Legg leaves his mark as historian and archæologist, he was for many years a learned and wise physician.

ANDREW ALEXANDER BROCKATT, M.D. BRUX., M.R.C.S.

Dr. Brockatt, of Great Malvern, who died in London on Oct. 24th, was in his fifty-eighth year. He entered St. Thomas's Hospital as a student in 1881, qualified in 1885, and then held house appointments there and at the Brompton Hospital for Consumption. Before settling down to practice he made several voyages as ship's doctor to India and China, and acted for a time as medical registrar at his own hospital. In 1889 he joined the late Dr. Thelwall Pike in practice basis of all infant foods; whether, if the article was imported for making milk-stout, it was exempt from duty; if so, would he state the reason for this discrimination; and whether the advisability of removing this article from the list altogether would be considered.—Mr. **BALDWIN** replied: Crude lactose, which is used in the manufacture of milk-stout, is not dutiable under any heading of the schedule to Part I. of the Safeguarding of Industries Act; the pure quality, which is used for the preparation of certain special foods, is dutiable as a fine chemical. As I have repeatedly stated, I have no power to exclude on any ground from the operation of the Act any commodity properly included within the general headings of the schedule, but the question whether lactose is properly so included can be referred to the Referee under Section 1 (5), and this, I understand, is being done.—Mr. **LAMBERT** asked whether the right hon. gentleman on May 12th last did not specifically state that food in the widest sense would be excluded from the schedule, and if so, why did he include it by administrative order?—Mr. **BALDWIN** said it was not correct to say that he had included food in the schedule by administrative order. The question whether refined lactose should come within the definition of food would be decided by the Referee.—Mr. **LAMBERT**: Is it not a fact that pure lactose is used in the preparation of infant food and surely it is a key industry?—Mr. **BALDWIN**: That is a matter for the Referee.

Medically Unfit Civil Servants.

Lieut.-Col. Sir **SAMUEL HOARE** asked the Secretary to the Treasury how many ex-Service temporary civil servants had been marked medically unfit for the permanent service.—Mr. **HILTON YOUNG** replied: The number of ex-Service candidates at the recent limited examinations who have been disqualified on medical grounds for permanent appointment is eight.

TUESDAY, NOV. 8TH.

Medical Stores for Russia.

On the report stage of a Supplementary Vote for the Foreign Office of £100,000 in respect of miscellaneous war services,

Lord **R. CECIL** said that the vote included a quantity of medical stores that were being sent to Russia. He wished to know a little more about the policy of the Government in this matter, and whether the Government still adhered to the view about the Russian famine expressed by the Prime Minister on August 15th, when he referred to it as an appalling catastrophe, and said that an international organisation ought to be set up to provide relief for Russia. Now the Government came to the House with a proposal not to send food to Russia, but medical supplies. He did not wish to underestimate the value of medical supplies, but the case was one of starvation, and if it was to be dealt with effectively, food should be sent.

Mr. **CECIL HARMSWORTH** (Under Secretary for Foreign Affairs), replying to the debate, said that the vote was something in the nature of a book-keeping arrangement, so that a quantity of medical stores, clothing, tinned meats, and other foodstuffs, in the possession of the Disposals Board, might be allocated for the purpose of relief in Russia in accordance with the decision of the Government. The value of these stores at present prices was perhaps something like £250,000. They were to be handed over, or have already been handed over, to the British Red Cross Society, to be allocated as they thought right, without any conditions whatever. He understood that the Red Cross Society was establishing bases at Riga and Novarissisk for the distribution of these stores. The Government were informed that these stores were perhaps the most useful they could contribute, but obviously they were by no means an adequate provision for the need represented by the large number of people who were now suffering from famine in Russia.

Approved Lunatic Asylums for Ex-Service Men.

Captain **LOSEBY** asked the Minister of Pensions the total number of lunatic asylums approved of by the Ministry of Pensions for ex-Service men and the number of such approved institutions which were run for private gain.—Mr. **MACPHERSON** replied: Approximately 240 institutions are under the control of, or have been approved by the Board of Control and the Ministry, and of these more than 60 are private establishments.

AT UNIVERSITY COLLEGE, LONDON, and the Medical School of University College Hospital the celebration of the anniversary of the Armistice will be held to-day, Friday, Nov. 11th, at 10.15 A.M. precisely. The roll of honour will be read and the "Last Post" will be sounded, when after two minutes' silence the chairman of the War Memorial Committee will present the medical memorial tablet to the Dean of the Medical School, and the Slade Memorial Tablet to the chairman of the Slade Committee. The tablets will be open to inspection during the day.

Medical News.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Final Examination of the Conjoint Board, held from Oct. 4th to 21st, the following candidates were approved in the undermentioned subjects, but are *not* eligible for diplomas:—

Medicine.—A. R. Abdel Razik, Cairo; M. Bienenstock, Budapest; A. M. F. Browne, St. Mary's; T. H. Cathrall, Oxford and London; Dorothy J. Collier, Oxford and Univ. Coll.; Dorothy A. D. Cropper, King's Coll.; J. G. Drew, Cambridge and St. Thomas's; A. C. D'Souza, Manchester; M. A. El Biblawi, Guy's; Mary C. Elliot, Univ. Coll.; Ena D. Foster, St. Mary's; Dora J. Fox, London; J. E. Gaze, Charing Cross; Nancy K. Gibbs, Univ. Coll.; T. J. E. Gittins, Birmingham; Alice M. F. Goldman, Univ. Coll.; B. O. Hancock, Birmingham; T. H. J. Hargreaves, Charing Cross; M. C. Hartley, London; Hilda M. Haythornthwait, Royal Free; G. H. Hogben and B. D. Hughes, St. Bart.'s; A. O. Jones, Liverpool; E. M. Jones and J. N. Kerr, St. Bart.'s; Lorna Susan King, St. Mary's; H. D. Lawson, London; K. W. Leon, St. Bart.'s; F. H. Mather, Cambridge and London; C. O. Minasian, St. Mary's; W. H. Nettelfield, St. Bart.'s; G. B. Oliva, Liverpool; Hilda W. Page, Univ. Coll.; Edith C. Phelps, Royal Free; Ruth E. Pilgrim, London; Sybil M. Rees and H. R. Rishworth, Charing Cross; R. Salib, Manchester; Olive M. Salmon, St. Mary's; T. A. S. Samuel, London; Gladys M. Sandes, Royal Free; S. Sandler, London; Norah B. A. Sankey, St. Mary's; Ena M. Sansom, Royal Free; Patricia H. S. Shaw, St. Mary's; K. E. Shellshear, St. Bart.'s; Eleanor C. E. Stone, St. Mary's; H. J. V. Sutton, Middlesex; R. S. Swindell, London; and E. H. Weatherall, St. Bart.'s.

Midwifery.—Janet K. Aitken, Royal Free; Ruth M. Arkwright, St. Mary's; C. W. C. Bain, Oxford and St. Thomas's; G. W. Ballance, Birmingham; F. Bentham and H. C. Berlie, St. Mary's; M. Bienenstock, Budapest; Gwendolen M. Brown, Charing Cross; Margaret M. Brownstone, Univ. Coll.; Grace D. Chambers, St. Mary's; Anaple Frances M. Christie, Royal Free; F. S. Coleman, St. Bart.'s; Dorothy J. Collier, Oxford and Univ. Coll.; Florence E. Cowlin, Charing Cross; M. Critchley, Bristol; B. B. Dalal, London; D. B. D'Alwis, Ceylon and Middlesex; Nancy B. Daniell, King's Coll.; F. J. Darbyshire, Westminster; S. Dewar, London; B. Dous, St. Bart.'s; J. G. Drew, Cambridge and St. Thomas's; Beatrice E. Ebden, London; W. C. Faull, St. Mary's; W. W. J. Fernando and G. Fraser-Smith, Middlesex; R. M. Fry, St. Mary's; Hilda M. Garlick, Royal Free; F. A. Gaydon, St. Thomas's; Nancy K. Gibbs, Univ. Coll.; Janet V. Good, London; S. Gordon, St. Bart.'s; J. H. H. Gough, Cambridge and St. Thomas's; Elsie C. Griffin, Dublin and Charing Cross; F. J. S. Hall, St. Mary's; A. G. Hammond, Middlesex; Kathleen M. D. Harding, St. Mary's; T. I. Hardy, Moscow and Royal Free; Doris J. Harston and M. C. Hartley, London; J. K. Hasler, Middlesex; Hilda M. Haythornthwait, Royal Free; M. M. Hegab, Guy's; Edith W. W. Hind, Univ. Coll; W. E. Howell, St. Bart.'s; F. C. Hunt, London; Winifred M. Jenkins, Royal Free; A. Jephcott, Cambridge and St. Bart.'s; R. Jones, Birmingham; Hilda M. Kennedy, Univ. Coll.; J. N. Kerr, St. Bart.'s; D. Krestin, London; Gladys M. Lambourne, St. Mary's; B. L. Laver, Guy's; B. J. Leggett, London; A. Q. Logan and J. N. Loring, St. Thomas's; G. S. Lund, Cambridge and St. Thomas's; Mary C. Lynch, St. Mary's; A. N. Macbeth, Univ. Coll.; Caroline G. L. McHardy, Royal Free; M. Mackenzie, Guy's; Gladys H. Marchant, Calcutta; P. de R. Mason, St. Mary's; J. K. Milward, Guy's; N. R. Mucadam, Bombay and Royal Free; R. W. Nichol and C. P. Oliver, Cambridge and St. Thomas's; G. E. Peacock, King's Coll.; J. H. Piddock, Birmingham; L. E. Pimm, King's Coll.; I. N. O. Price, London; A. B. Rao, Middlesex; Sybil M. Rees, Charing Cross; Hilda E. Reynolds, Bristol; Z. Salama, Birmingham; Olive Metcalfe Salmon, St. Mary's; J. S. Salt, Charing Cross; E. F. Smith, St. Thomas's; N. R. Smith, Sydney; Emma M. Store, Royal Free; M. H. Summers, Middlesex; Mary I. Symons, London; H. W. Taylor, Cambridge and Guy's; W. J. Verheyden, Univ. Coll.; W. J. Vickers, Birmingham; A. J. Vickery, St. Mary's; Hygeia L. J. Wallace, Charing Cross; W. R. Ward, St. Bart.'s; F. W. Widgery, Guy's; Cordelia I. Williamson, Charing Cross; C. P. Wilson, Middlesex; and W. A. Young, St. Thomas's.

Surgery.—A. R. Abdel Razik, Cairo; S. Ackroyd, Leeds; W. F. Attwater, Cambridge and Guy's; Mary H. Y. Blakeston, Royal Free; W. R. Carling, Cambridge and Guy's; A. J. Chiappa, Middlesex; K. A. Darukhanawala, Bombay and St. Thomas's; Sheila Dewar, N. Gallant, and J. H. Gann, London; W. Girgis, St. Mary's; S. Gordon, St. Bart.'s; E. F. Griffith, St. Mary's; B. Kessel, Guy's; H. D. Llewellyn, Cardiff and St. Bart.'s; Caroline G. L. McHardy, London; G. G. Michell and R. E. Overton, Univ. Coll.; G. E. Peacock, King's Coll.; Evelyn V. Pillers, St. Mary's; L. E. Pimm, King's Coll.; A. E. Roche, Cambridge and St. Bart.'s; Gladys Rutherford, Liverpool; C. Satyaraju, Madras and London; Y. S. Soliman, St. Thomas's; E. C. A. Wilson, London; and A. D. Wright, St. Mary's.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The thirty-fourth annual general meeting of Fellows and Members will take place at the College, Lincoln's Inn-fields, W.C., on Thursday, Nov. 17th, at 3 P.M. The following resolutions

INTERNATIONAL LABOUR CONFERENCE AT GENEVA.

(FROM A MEDICAL CORRESPONDENT.)

THE real significance of the appearance of medical items in the programme of the Third International Labour Conference lay not so much in the particular subjects under discussion as in the precedent which is created by the consideration of problems of industrial medicine in the public forum of what may be regarded as a form of international parliament. At the time of writing it is doubtful whether any convention will be agreed upon as regards the use of white lead in paint, and it is almost certain that no convention will be passed at this session for the disinfection of anthrax-infected wool. On the other hand, the attention of employers and governments the world over has been drawn to these two problems and from this fact alone much profit will certainly accrue. But the future of these conferences is pregnant with possibilities much greater than that of the elimination of anthrax from the wool trade. Supposing that merchant seamen should demand an investigation into the prevention of ship-borne plague, or some grinders' union obtain from the Labour Bureau the preparation of a draft convention concerning the use of the old-fashioned sandstone wheel which is responsible for preventable silicosis, measures of capital importance to the health of workers in almost every land might at once be inaugurated.

The Debate on Anthrax.

The measures taken by the British Home Office have been continually referred to in the special anthrax commission now sitting. It may be recalled that the departmental committee appointed to inquire as to the precautions to be taken for prevention of danger from anthrax in the manipulation of wool, goat hair, and camel hair, reported that " precautionary measures are insufficient and that complete protection can only be afforded by disinfection of the raw material before it enters the factories " ; and that subsequently a government disinfecting station was established at Liverpool. The draft convention of the Labour Office, drawn up after consideration of the replies of various governments to a questionnaire, contains provisions for the establishment of an international anthrax commission which would prepare a schedule of suspected wools—" wool " for the purposes of the convention being defined as " sheep's wool, camel hair, and goat hair." Article 7 contains the gist of the proposed convention and runs as follows :—

> Each member which ratifies this convention engages to prohibit the importation of wools included in the " Schedule of Suspected Wools " unless it is satisfied that such wool has been efficiently disinfected at the exporting port, or unless it has made arrangements to secure its efficient disinfection at the importing port.

The administrative difficulties of such a measure are recognised. The Indian representatives made it clear that it is impossible to control the importation of infected wool over 1600 miles of frontier, while to disinfect at the export stations would be an extremely difficult and costly undertaking. Great Britain, it would seem from the discussion, is the only country which uses infected wool to any considerable extent, though as a British delegate remarked, if Great Britain takes effective measures to keep infected wool out of the country the problem will soon affect other nations. The effect of disinfection on the wool itself was a subject of much controversy. While Colonel Foster claims from experience that the disinfected wool is improved in quality, others were disposed to believe that it is sold at a higher price merely because the cost of disinfection has to be added. It seemed to be generally agreed that disinfected wool cannot be " sorted " ; at the same time, it was stated that small risk from " wool-sorters' disease " attends the sorting of better quality wools. More than one delegate pointed out the desirability of attempting to stamp out anthrax at its source, though again the practical difficulties of doing this, especially in the more dangerous eastern countries, appear to be almost insuperable. At the time of writing it seems probable that a permanent commission, representing at least Great Britain, France, and Germany as manufacturing countries, Australia, India, and South Africa as producers, and possibly also Italy and the United States of America with an office in London, will be constituted to inquire into all these problems with instructions to report to the next Conference in 1923.

White Lead in Paint.

On the agenda paper discussion is to be taken in the following order—viz., medical, economic, technical, operative painters. As to the necessity and technical possibility of replacing white lead by zinc oxide in paint, agreement is unlikely at the present Conference. The diagnosis of plumbism was discussed for several hours, almost entirely by medical experts, among them Sir KENNETH GOADBY and Dr. T. M. LEGGE (Great Britain), Dr. LEYMANN and Dr. K. P. LEHMANN (Germany), and Dr. GILBERT (Belgium). The last-named laid much emphasis on the diagnostic importance of the discovery of basophilia. He considered that if large numbers of men in a given industry were found to have basophilic granulation that would prove that industry to be extremely dangerous. Prof. LEHMANN agreed with this significance of the blood observations. Sir KENNETH GOADBY brought forward some evidence of the fallibility of the test and the difficulty of differentiating between the basophilia of lead absorption and that due to malaria. Classifying cases of lead poisoning into two groups, an " explosive " type with classical symptoms and lead absorption accompanied by elimination, he argued that the granulations might well result from the passage of lead through the system in the second type. A medical subcommittee was then appointed to report on the capability of medical science at the present time to recognise plumbism. After sitting in camera this subcommittee reported as follows :—

> Medical science has been able for a long time to diagnose satisfactorily typical and severe cases of plumbism. Modern methods of diagnosis in the hands of specially trained medical men enable them (1) to recognise plumbism in most doubtful cases ; (2) to exclude cases of wrongly alleged plumbism ; (3) to recognise lead absorption and lead poisoning at an earlier stage than heretofore.

There is little, if any, dissent from Sir Kenneth Goadby's attempt to prove that while lead poisoning is an occupational disease it takes a relatively unimportant place among occupational diseases in general and the diseases to which painters in particular are liable. The fate of the draft convention to prohibit the use of white lead in paint is still in doubt.

Congress of Working Women.

The discussions of this international congress, held in Geneva from Oct. 19th–25th, were largely concerned with the subjects to be dealt with subsequently at the Labour Conference. The following extracts from their resolutions may be of interest :—

> *Children on Board Ship.*—All children should be subject to a medical inspection before being accepted in industry or commerce, but no child should be employed on board ship without the most rigorous medical examination. Since they are obliged to leave their families for an indefinite time, from a humanitarian standpoint it is necessary that they should be in perfect health during this period of separation.
>
> *White Lead in Painting.*—This Congress demands the immediate prohibition of the use of white lead in painting and for manufacturing uses. To require periodical medical examinations, public reports, and as wide publicity as possible to make known the extent of the ravages caused by this industrial poison.
>
> *Anthrax.*—It is desirable that wool should be subject to efficient disinfection as near the source of origin as possible : (*a*) while in the hands of the grower, (*b*) or when accumulated by the exporter, (*c*) and certainly prior to embarkation.
>
> *Agriculture.*—Agricultural workers must not sleep in barns and stables. Each worker must be provided with a bed. Every facility for medical assistance for women and children must be provided in rural districts.

Geneva, Nov. 5th.

St. Bartholomew's Hospital was represented by a series of tableaux in the Lord Mayor's Show on Nov. 9th.

SOCIETY OF M.O.H.'S: TUBERCULOSIS MIDLAND SUB-GROUP.—The second general meeting of this sub-group will be held at the Anti-Tuberculosis Centre, 44A, Broad-street, Birmingham, on Dec. 3rd, at 3 P.M. All members of the society are invited to attend. The agenda will include the presidential address: Some Remarks on the Differential Diagnosis of Pulmonary Tuberculosis; confirmation of the committee's selection of two representatives to the central council; and arrangements of dates and places for future meetings.

MALTHUSIAN LEAGUE.—On Nov. 9th a pre-maternity, maternity, and child welfare centre will be opened at 153A, East-street, Walworth, London, S.E., by the League. Two doctors and a doubly certificated nurse will be available at this clinic, where medical advice will include instructions on matters of restriction and spacing of births whenever the circumstances clearly indicate that on medical, hygienic, eugenic, or economic grounds such instruction is necessary.

LADIES' MEDICAL GOLFING SOCIETY.—A successful meeting was held at Oxhey Golf Club on Nov. 8th. In the morning a medal round was played. Mrs. V. Hetherington won the scratch prize with a score of 94; the prize presented by Mrs. Lewis Smith for the best net score was won by Mrs. E. H. Kettle with a score of 83, and Lady Rigby's prize for the best net score in the senior division was won by Miss Edith Adams with a score of 85. In the afternoon a nine-hole foursomes competition against bogey resulted in a tie between Mrs. Grainger Harrison and Miss M. Marshall (1 down) and Lady Goadby and Mrs. W. F. Peller (1 down).

CHELSEA CLINICAL SOCIETY.—The annual dinner was held at the Café Royal, Piccadilly, on Oct. 25th. Sixty-five members and guests were present. In proposing the health of the society, Mr. James Berry, the President of the Medical Society of London, congratulated the Society on its attaining its majority on that evening and on the good work done at its meetings. Dr. D. M. Barcroft, the President, replied, and later proposed the health of the guests, to which toast Sir Lenthal Cheatle, the President of the West London Medico-Chirurgical Society, Mr. Russell Howard, and the President of the Hunterian Society replied. Dr. G. de Bec Turtle, President of the Harveian Society, proposed the health of the President of the Chelsea Clinical Society, and Dr. Barcroft responded.

ULSTER MEDICAL SOCIETY.—The opening meeting of the session was held on Nov. 3rd. Dr. T. Houston, the outgoing president, took the chair at the beginning of the proceedings, and introduced his successor, Dr. Robert Hall, who proceeded to deliver his inaugural address on "Unusual Cases of Pulmonary Disease." The address contained a digest of the speaker's experience. The President subsequently unveiled a tablet containing the names of the members of the Society who had served in the late war, the gift of Dr. H. L. McKisack. A vote of thanks to the donor was cordially passed on the motion of Prof. J. A. Lindsay, seconded by Prof. R. J. Johnstone.

LITERARY INTELLIGENCE.—A new series of volumes to be published by Messrs. George Routledge and Sons, under the title Twentieth Century Chemistry, is in preparation under the editorship of Sir William Tilden, D.Sc., F.R.S., Emeritus Professor in the Imperial College of Science and Technology, South Kensington, and Dr. J. C. Philip, F.R.S., Senior Secretary of the Chemical Society and Professor of Physical Chemistry in the Imperial College. The intention is to provide works of moderate size and price, which, without being exhaustive monographs, will furnish advanced students with a complete survey of the present state of knowledge and opinion in each branch of the science. Several distinguished British and foreign chemists have promised to contribute volumes to the series.

AUXILIARY ROYAL ARMY MEDICAL CORPS FUNDS. The usual quarterly committee meeting was held on Oct. 28th, at 11, Chandos-street, London, W. Six grants were made to cases in the benevolent branch for the orphans of officers, amounting to £158, and 46 grants in the relief branch for widows and orphans of the rank and file, amounting to £1366. These funds exist for the relief of widows and orphans of commissioned officers, non-commissioned officers, and men of the rank and file of the Royal Army Medical Corps, Special Reserve, Territorial Force, and New Armies, and also for the relief of those who have been so severely damaged in the late war that they need help for the education of children. Requests for relief should be addressed to the hon. secretary at the offices of the funds, 11, Chandos-street, Cavendish-square, London, W. 1.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting will be held in the board-room of the Miller General Hospital, Greenwich, to-day, Friday, at 8.45 P.M. Dr. C. T. T. Comber, the president, will occupy the chair and Mr. P. B. Roth will deliver an address on Treatment of Fractures.

DUBLIN UNIVERSITY BIOLOGICAL ASSOCIATION.—The opening meeting of the Dublin University Biological Association was held last Saturday evening, when Dr. J. Speares, President, read a paper on Some Experiences of Vaccine Therapy. The paper was discussed by Drs. A. C. O'Sullivan, J. T. Wigham, H. S. Sugars, and Mr. K. L. G. Gunn.

SAFEGUARDING OF INDUSTRIES ACT.—The Board of Trade have received a formal notice of complaint from the Eastern and Russian Trading Company, of 8, Drapers-gardens, Throgmorton-avenue, London, E.C. 2, that santonine has been improperly included in the lists of articles chargeable with duty under Part I. of the Act.

NATIONAL PROVIDENT SCHEME.—A meeting, open to all members of the medical profession and specially to the medical staffs of hospitals, arranged by the Marylebone Division of the British Medical Association, will be held at 8.30 P.M., on Nov. 16th, at 11, Chandos-street, London, W., when Mr. W. McAdam Eccles will move: "That this meeting of medical practitioners in the Marylebone Division of the British Medical Association approves in general of the National Provident Scheme for Hospital and Additional Medical Services," and Dr. C. O. Hawthorne will oppose. Thereafter discussion will be open.

HONOUR TO A MEDICAL MAN.—The town council of Oldham has resolved unanimously to confer the honour of the freedom of the borough upon Dr. Thomas Fawsitt, who for over half a century has rendered service to the citizens of Oldham as a surgeon in the Royal Infirmary, for some time chairman of its governors, and in his extensive private practice before his retirement. Dr. Fawsitt still continues to take a lively interest in the infirmary. A public subscription is being set on foot to raise funds to endow a bed in the infirmary to commemorate his name.

THE LATE DR. R. P. WOODROOFE.—Richard Percy Woodroofe, who died at Eccleshill, Bradford, on Oct. 24th, aged 58, came of a family of doctors and was born at Dublin, where he received his early education. He also studied at Yorkshire College, and in 1884 qualified with the L.A.H. Dub. and the L.M. of the Coombe Hospital. Ten years later he obtained the L.R.C.S.I. and L.M. Starting his medical career as surgeon and medical assistant at the Mercers Hospital, Dublin, he settled in Yorkshire, becoming medical officer at Eccleshill, and taking a full share in local medical politics.

N.C.C.V.D. SCOTTISH COMMITTEE.—A Conference of representatives of the local authorities of Scotland is to be held in the City Chambers, Glasgow, on Friday, Dec. 2nd, to discuss various aspects of the venereal diseases problem preparatory to the undertaking of an active educational campaign throughout the country. The Conference is being organised by the Scottish Committee of the National Council, of which Dr. McGregor-Robertson is chairman and Mr. W. E. Whyte secretary. Sir Malcolm Morris, a vice-president of the Council, Sir Leslie Mackenzie, medical member of the Scottish Board of Health, and other prominent representatives of Local Government activities in Scotland, will take part in the proceedings, over which Lord Provost Paxton presides.

HARROGATE MEDICAL SOCIETY.—The second meeting of the session was held at the clinical laboratory, by permission of Dr. Sinclair Miller and Dr. F. B. Smith, on Oct. 20th. Dr. A. Mantle presided and there was a large attendance of members. Part of the evening was devoted to the examination and discussion of pathological specimens from recent cases of clinical interest. Dr. Miller read a paper on Basal Metabolism, and this was followed by a demonstration of the Portable Benedict Apparatus by Mr. Kendrick, of the Sanborn Company, London. Dr. W. Bain, Dr. W. Edgecombe, Dr. G. W. S. Saberton, Dr. Bertram Watson, and others discussed the paper and the value of the apparatus as applied to clinical work.—At a meeting on Nov. 3rd a paper was read by Mr. A. B. Pavey-Smith, F.R.C.S., entitled Some Remote Effects of Tonsillitis. The evidence, experimental and clinical, pointing to the tonsil as an important focus of infection in systemic disease was reviewed, and the diagnosis of latent chronic tonsillitis described. A discussion followed, concerned especially with arthritis and its connexion with tonsillar infection.

The Supply of Milk for Mothers and Children.

Sir **ROBERT NEWMAN** asked the Minister of Health whether in consequence of Circular No. 185, issued by the Ministry of Health on March 31st, 1921, the powers of local authorities to supply milk to mothers and children had been considerably curtailed, with the result that this winter, when great distress and suffering was likely to be experienced owing to unemployment, the local authorities would not be allowed to supply as much milk to mothers and children as last year when conditions were more favourable; and whether, in view of the importance of protecting child life, he would consider the advisability of restoring to the local authorities the discretionary powers they possessed under the Milk (Mothers and Children) Order, 1919, before those powers were curtailed by the circular issued last March.—Sir A. **MOND** replied: The conditions imposed by Circular 185 were designed mainly to ensure that milk should be supplied only to necessitous cases, and it is not anticipated that they will result in any appreciable reduction of the amount supplied in each case. Recent estimates indicate that the expenditure of local authorities on milk has increased under the new conditions. The Milk (Mothers and Children) Orders, 1919, extended the supply to other than necessitous cases. These orders were made under powers conferred by the Defence of the Realm Regulations, which have now lapsed, and in any case their restoration would not assist the persons whom my hon. friend has in mind.

Medical Officers of Bradford Corporation.

Mr. **RATCLIFFE** asked the Minister of Health if he was aware that the Bradford corporation employed 33 full-time medical officers; what their annual salaries amounted to; how did this number compare with other towns of a similar size and population; how did the amount of their salaries affect the taxpayer; and could he take any steps to reduce this number.—Sir A. **MOND** replied: I have not full information as to the total number of medical officers employed by the corporation of Bradford. I am concerned only with those whose salaries are a charge on grants administered by my department, and I am now in communication with the Bradford corporation as to this portion of the staff.

Summer Time and School-children.

Major **KELLEY** asked the President of the Board of Education whether his department had obtained the opinion of education authorities with regard to the effect of summer time on school-children; and whether their opinion was in favour of its continuance.—Mr. J. **PARKER** replied: The Board have not yet received replies to their circular of May 24th from all the local education authorities, but of the 272 authorities who have replied a majority (158) are in favour of the continuance of the Summer Time Act, 29 expressed no definite opinion, and while 85 attribute some ill-effects to the operation of the Act, the great majority of those authorities take the view that they would be obviated if the parents would send the children to bed at a reasonable hour.

Approved Societies and Medical Benefit.

Mr. **TREVELYAN THOMSON** asked the Minister of Health what reduction he proposed to make in the levy of 9*s.* per member required from approved societies on account of medical benefits, seeing that doctors' fees had now been reduced from 11*s.* to 9*s.* 6*d.* per member.—Sir A. **MOND** replied: The present cost of medical benefit is 13*s.* 9*d.* per head. Nine shillings and sixpence is charged to Insurance Funds, to which the Exchequer contributes the statutory two-ninths. The excess cost of 4*s.* 3*d.* per head is met by a special Exchequer grant. The saving due to a reduction in doctor's fees must clearly go in relief of the excess cost charged to the Exchequer.

Testing of Clinical Thermometers.

Mr. **JESSON** asked the President of the Board of Trade whether clinical thermometers of foreign manufacture would be accepted for testing at the National Physical Laboratory; and whether the Government would insist that such thermometers be marked with the country of origin, as well as the letters N.P.L., in order to prevent the assumption that they were of British manufacture, with a view to safeguarding the British industry.—Sir **WILLIAM MITCHELL-THOMSON** replied: The answer to the first part of the question is in the affirmative. I am advised that the standardisation mark of the National Physical Laboratory, which is registered under the Trade Marks Act, is and has always been intended to convey a certificate of the accuracy of the articles marked. The Laboratory are not in a position to determine or certify the origin of thermometers presented to them for marking. The question of the requirement of an indication of origin in the case of clinical thermometers is part of the large question of the compulsory marking of foreign goods generally which will be dealt with in the Bill to amend the Merchandise Marks Act which His Majesty's Government have undertaken to introduce.

THURSDAY, NOV. 3RD.

Bellahouston Hospital Report.

Mr. **DUNCAN GRAHAM** asked the Minister of Pensions whether it was his intention to circulate the report of the committee who inquired into the conditions obtaining in Bellahouston Hospital; and, if so, when it would be circulated.—Mr. **MACPHERSON** replied: The report will be published and placed on sale at the earliest possible date. I will arrange to supply my hon. friend with a copy if he so desires.

Institutional Treatment of Tuberculous Ex-soldiers.

Mr. **TREVELYAN THOMSON** asked the Minister of Pensions what steps had been taken and were being taken by his department to indemnify local insurance authorities for the expenses incurred by them for the institutional treatment of ex-Service men whose appeals for pensions on account of tuberculosis had been upheld after the Ministry had declined liability, and ceased payments for institutional treatment.—Mr. **MACPHERSON** replied: The expenses of residential treatment for ex-Service men suffering from tuberculosis are settled directly between my department and the Ministry of Health, in accordance with preferential arrangements applicable to ex-Service men, and subject to a mutual arrangement entered into between the two departments. I am not aware that there has been any failure to deal with the claims referred to in the question in accordance with the agreement reached.

Small-pox in Glasgow.

Mr. **ROBERT YOUNG** asked the Secretary for Scotland if he would ascertain from the medical officer of health for Glasgow how many of the children under 10 years of age who were attacked by small-pox in the outbreak in 1920 belonged to families living in one room, two rooms, three rooms, and four rooms and upwards, respectively; and whether any, and, if so, how many, of the fatal cases came from such families.—Mr. **PRATT** replied: The figures in reply to the first part of the question are respectively 13, 66, 13, and 2. Of these, 5, 18, 6, and 2 respectively were fatal cases. These figures exclude 4 cases from beyond the city boundary.

Soldiers and Venereal Disease.

Major **COLFOX** asked the Secretary of State for War what number of soldiers suffering from venereal disease were treated in barracks or auxiliary hospitals, and were not calculated in the official returns.—Sir L. **WORTHINGTON-EVANS** replied: All soldiers suffering from venereal disease are admitted to hospital and are treated in hospital till active signs of the disease have disappeared and they are fit to return to duty. All such cases are included in the official statistical returns. Cases of syphilis have subsequently to undergo a prolonged course of out-patient treatment in barracks, but they are not included in statistical returns after their discharge from hospital unlsss readmission is necessary, when they are again included in the returns.

Major **COLFOX** asked the Secretary of State for War what had been the incidence in rates per 1000 per annum of venereal disease amongst British troops in the United Kingdom, in the Army of the Rhine, and in the Army of the Black Sea, for 1919, 1920, and the first half of 1921.—Sir L. **WORTHINGTON-EVANS** replied: In the subjoined table the figures shown between brackets for 1919 are those which were given under reserve on May 18th in reply to Capt. Elliott. It is now clear, however, that, owing to the rapidity of demobilisation and to other circumstances, they are quite unreliable. No figures for 1919 are available for the Black Sea.

Area.	Annual rate per 1000 of strength.		
	1919.	1920.	January to June, 1921.
United Kingdom	[59]	48·30	38·03
Army of Rhine	[46]	188·61	148·90
Army of Black Sea ..	—	213·73	238·94

MONDAY, NOV. 7th.

Import of Pure Milk Sugar.

Mr. **LAMBERT** asked the President of the Board of Trade if he was aware that one firm in this country uses from 25,000 to 30,000 gallons of milk per week in the preparation of infants' food and that pure milk sugar, an essential ingredient not produced in this country, was subjected to a 33⅓ import duty; and whether, seeing that such a duty would discourage milk production and increase the price of infants' food, he would at once cancel the duty.—Mr. **MYERS** asked the President of the Board of Trade whether sugar-milk, British Pharmacopœia, had been entered as liable for duty under Part I. of the Safeguarding of Industries Act; whether he was aware that this article was an essential

WEDNESDAY.—10 A.M., Dr. Parkinson, and 2 P.M., Dr. Moon: Out-patients.

THURSDAY.—2 P.M., Dr. Price: Out-patients. Dr. Moon: In-patients. 6.30 P.M., Dr. Hamill: Out-patients.

FRIDAY.—10 A.M., Dr. Parsons-Smith: Out-patients. 2 P.M., Dr. Parkinson: Out-patients. 3 P.M., Dr. Parkinson: In-patients. 4 P.M., Dr. Goodall: In-patients.

SATURDAY.—10.30 A.M., Dr. Hamill: In-patients.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 17th.—4 P.M., Lecture:—Dr. F. J. Poynton: Medical Calamities in Childhood.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.

THURSDAY, Nov. 17th.—6 P.M., Chesterfield Lecture:—Dr. W. K. Sibley: Electrical Treatments, Ionisation, &c.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Nov. 15th.—4.30 P.M., Dr. C. H. Melland: Prognosis and Treatment of Pernicious Anæmia.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURES, at Whitworth-street, West Branch, Manchester.

FRIDAY, Nov. 18th.—4.30 P.M., Mr. Morley: Abdominal Tuberculosis.

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street, Whitworth Park.

Special Terms for Position Pages.

will be sent in to the President and Council on behalf of the Society of Members of the College :—

(1) "That this thirty-fourth annual meeting of Fellows and Members again affirms the desirability of admitting Members to direct representation on the Council of the College, which (as now constituted) only represents those Members who also hold the Fellowship; and that it does so in order that the constitution of the Council of the Royal College of Surgeons of England shall be in keeping with modern ideas of true representation."

(2) "That as the Royal College of Surgeons is composed of about 18,000 persons, of whom over 16,000 are engaged in general practice, this annual meeting requests the President and Council to nominate *at least* two Members in general practice to represent the interests of general practitioners in the management of College affairs."

(3) "That this meeting of Fellows and Members earnestly requests the President of the College to make a detailed statement *here and now* as to all the reasons, legal and otherwise, for the Council persisting with a refusal to allow representation on the Council of the Members in general practice; and to state definitely whether legal advice has been taken as to any possible means of overcoming any difficulties in the way of carrying out our wishes; and, if so, to declare what that advice was."

THE sum realised at the Manchester University bazaar is stated to be likely to reach £15,000.

UNIVERSITY OF EDINBURGH.—On Nov. 4th the fourteenth annual dinner of Edinburgh University Graduates' Club was held at Tilley's Rooms, Newcastle. Dr. D. W. Inglis (Hebburn), president of the club, occupied the chair. The guest of the evening was Sir J. Alfred Ewing, F.R.S., Principal of the Edinburgh University. Amongst others present were Dr. David Drummond (Vice-Chancellor of the University of Durham and President of the British Medical Association), Dr. Harold Kerr (Medical Officer of Health for Newcastle and hon. treasurer of the club). The President proposed the toast of Alma Mater; in his reply Sir J. Alfred Ewing stated that a very satisfactory feature of university life was the keenness and energy with which men returned from the war had resumed their studies. The presence of women in the university, he thought, had done no harm. At Edinburgh they were now engaged in building what he considered would be the finest chemical laboratory in the country. Alluding to the expense of training, he remarked that the cost of education at Edinburgh had recently been found to be slightly lower than any other, and its efficiency was second to none. Last year the total Government grant to universities was increased to one and a half million sterling, but they had been told that the grant was to be diminished by £200,000 next year. Moreover, they had to do all they could themselves, and he urged the necessity for voluntary financial support. The toast of Sister Universities was given by Dr. J. Wilkie Smith, who said it was a great pity that two such colleges as Armstrong College and the College of Medicine in Newcastle should be hampered by want of funds. Responding, Dr. David Drummond paid a tribute to the "city of their adoption," and emphasised the need for men of sound common sense at the head of the universities.

UNIVERSITY OF BRISTOL.—An unusual means of awakening public interest in the necessity for increased monetary support of the universities has been utilised by the Appeal Director of the University of Bristol Appeal Fund, in the form of a 48-page pamphlet containing about 150 excellent sepia reproductions of photographs of the university, of its associate colleges and surroundings, and of scenes representing practically every side of university life. The claim is made in a footnote that "at no university in the world do students secure greater facilities for being brought into touch with the practical affairs of life." A sum of £10,000 has been received in support of this appeal from the Imperial Tobacco Co. (of Great Britain and Ireland), Ltd., Bristol, also a sum of £1000 from the Directors of the National Provincial and Union Bank of England, Ltd.

PAYMENTS BY HOSPITAL PATIENTS IN BRISTOL.—The two large general hospitals of Bristol have now had some little experience of the system inaugurated this year of collecting payments from patients to meet excessive financial strain. Speaking at the General Hospital the other day the chairman, Mr. Herbert M. Baker, explained that the sums collected from patients represented only a fraction of the total cost. The average cost per bed per week was over £3, while the sum asked from each patient is but one guinea per week. He was able to report the gratifying fact that contributions from workpeople had increased instead of falling off as had been expected. At the Royal Infirmary, whose president, Mr. Henry Wills, has just resigned owing to ill-health, the almoner reported that only one in five of the patients admitted is able to pay the small contribution asked for. It is therefore clear that some other form of collection of income must be devised if these institutions are to be established on a sound financial basis.

PHYLLIS SIEPMANN MEMORIAL PRIZE.—Miss Phyllis Siepmann, a daughter of a Clifton College master and a student in the Faculty of Medicine of Bristol University, recently died of septicæmia while acting as a surgical dresser at the Royal Infirmary. In her memory her brother, Mr. Henry Arthur Siepmann, has established an annual prize of the value of £50 for the third-year student at the infirmary who shall secure first place in an examination in medicine and surgery, with special reference to diseases of children.

DIPHTHERIA IN BRISTOL.—A memorandum issued by Dr. D. S. Davies (M.O.H. Bristol) and Dr. B. A. Peters (resident medical officer, Bristol City Fever Hospital, Ham Green) to medical practitioners in Bristol, calls attention to the occurrence within the city of cases of diphtheria of an unusually virulent type. The formation of membrane is much delayed, often till two or three days after the onset of œdema of the fauces and neck. Occasionally the fauces escape almost wholly, the infection attacking the naso-pharynx and provoking a sanious or purulent rhinorrhœa. The memorandum urges practitioners to give large doses of antitoxin as soon as symptoms are manifest. Few of the patients survive if this is delayed beyond the first 48 hours; early treatment is rendered the more necessary by the deceptive mildness of the initial symptoms. There is often no local pain, the child complaining only of headache or sickness, and pyrexia is usually slight and of brief duration. Cases of primary conjunctival and vulvar infection have been seen. A circular has also been issued to the local profession announcing that a demonstration of the disease will be given by Dr. Peters, who is also the university lecturer on Fevers, to any practitioners who apply for tickets to the Director of Post-Graduate Studies, Faculty of Medicine, University of Bristol.

THE ROYAL MEDICAL BENEVOLENT FUND GUILD.—A sale of Paris millinery, fancy articles, garden produce, and other useful and attractive commodities will be held at 9, Wetherby-gardens, London, S.W. 5, on Thursday next, Nov. 17th, from 10 A.M. to 6 P.M., in aid of the Royal Medical Benevolent Fund. It is hoped that readers of THE LANCET will bring this sale to the notice of their patients.

The Guild is a branch of the Fund, formed to assist distressed members of the medical profession, their wives, widows, or families by: (1) Personal service; (2) providing clothing; (3) giving educational or other help as recommended by the General Purposes Committee of the Guild; (4) promoting any other work which may seem desirable, or may be approved by the Executive Committee of the Fund; (5) by gifts of money. Clothing is urgently required for men, children, and ladies, both old and young—especially the latter; and there are numerous directions in which any money realised by the sale can be expended usefully. The visiting secretary of the Fund investigates all cases and reports to headquarters, who, on being satisfied, allocate the suitable form of aid. Communications may be addressed to Mrs. Violet L. C. Cotton, at 9, Wetherby-gardens, S.W.

POOR-LAW REFORM IN IRELAND.—During the past six months an extensive and far-reaching reform of Poor-law administration has been going on in the greater part of Ireland. The county councils and other local authorities in nearly all southern Ireland had repudiated the authority of the Local Government Board and had been deprived of the Treasury grants ordinarily paid for health services. Acting on the advice of the Local Government Department of Dail Earann, the several authorities in each county came together and in conference decided on a scheme of Poor-law and health reform for their county. Most of the counties in the three southern provinces of Ireland have now constructed their schemes, and are gradually getting them into working order. Much local opposition has been avoided owing to the poverty of the local authorities consequent on the diversion of the Treasury grants, and Dail Earann has taken skilful advantage of this poverty to press forward its schemes of reform. Although the schemes in the different counties vary somewhat in detail, they are in general conformity to one model. All workhouses as such are abolished, and one county home is established to house the aged or infirm inmates of the workhouses. Boarding-out of children is encouraged, but in some counties there is provision for a children's home. The hospital system of the county is to be organised on the basis of one county hospital in each county, with, in large counties, one or more district hospitals. The Poor-law medical relief system is not altered. The administrative area is to be the county. Our Irish Correspondent adds: On the whole, the reforms appear to be on sound lines, and are very similar to those proposed last year by the Irish Public Health Council and 15 years ago by the Vice-Regal Commission. The chief drawback in the present reforms is that they are on a county, not on a national basis.

"LA FRANCE."

UNDER this title a review of the French press is appearing weekly, published by Messrs. Evans Brothers, Ltd., at Montague House, Russell-square, London, W.C. The paper consists partly of extracts from the best French newspapers, and partly of short articles designed to interest English readers in an intimate manner with French life and manners. Parents whose children are studying French will be glad to know of a paper which they can obtain each week for their children and which they can place fearlessly in their hands; while the pages will form an excellent and interesting way by which a general public can keep up its knowledge of French.

THE USES OF DOG (CYNOTHERAPY).

To the Editor of THE LANCET.

SIR,—Interesting details with regard to what may be termed cynotherapy have appeared in recent issues of THE LANCET (Oct. 8th, p. 786, and 22nd, p. 884), information being gleaned from France of the eighteenth century and from Mesopotamia of the tenth. It is not, however, necessary to go so far afield either in time or place to find this sort of thing in folk-medicine. Apparently in the 1763 edition of the "Pharmacopée Universelle" there were directions as to ointment, oil, and liniment prepared from dogs, the liniment being made use of for sciatica and rheumatism. In the present year I have heard more than once in Manchester of some stuff called dog oil. One man, crippled by rheumatoid arthritis, has even obtained a supply of this material for local use from one of his friends—I have not seen it, however. In South Yorkshire, too, I hear of its employment in Ecclesfield and in Sheffield.

Inquiries fail to reveal how this dog oil is prepared nowadays; if it is really an oil it can hardly be the natural fat of the dog, as this, like mutton fat, solidifies after death of the animal in temperate climates. A herbalist from whom I asked information, knows nothing of this dog oil, though stocking mandrake and dragon's blood (or should one write it as dragons' blood?) on her shelves, but suggests that as oil of swallows does not come from swallows, this dog oil may perhaps have nothing to do with dogs, but may really be some vegetable product, instancing dog roses, dogwood, and dog violets in support of this notion. Whatever its real nature, it would appear to have a wonderful reputation in the folk-treatment of joint affections of various kinds, and as proof of its efficacy they say that "it's so strong that it will even go through iron!"

With regard to the lick of the dog as a healing agent (which I suspect to have arisen owing to the misunderstanding of a scriptural incident, Lazarus succumbing under the treatment), I heard a couple of years ago in County Durham of a whole family ascribing their recovery from scabies to their sores being licked by a pet dog.

I am, Sir, yours faithfully,

Manchester, Nov. 6th, 1921. W. J. RUTHERFURD.

To the Editor of THE LANCET.

SIR,—Allow me to add to what has been published in THE LANCET of Oct. 8th and 22nd concerning the uses of dogs in medicine, that Hippocrates, speaking of phthisis, says that consumptives must eat *σκυλακίσιον κρέας* or dog's meat.

I am, Sir, yours faithfully,

S. C. ZAVITZIANOS.

CANINE DISTEMPER.

IN regard to an epidemic disease recently fatal in South Wales, there seems no reason to doubt that it was a specially virulent brand of distemper, concerning which we know about as much or as little as we know of measles in the human subject and its ætiology. Although the causative organism of distemper in the dog has not been isolated, evidence is growing that the disease is due to a filtrable virus analogous to that of equine influenza, swine fever, and fowl plague. Associated in some way with the disease, whether as mixed infection or as predisposing factor, are the *Bacillus bronchisepticus* (Ferry) and various strains of staphylococci and streptococci. Subcutaneous injection of the serous discharge from the nose of affected dogs kills young animals in six to seven days. Natural infection occurs through direct or indirect contact with affected animals. Young dogs in the second half-year of life are chiefly affected, but dogs of any age may contract the disease and one attack does not confer complete immunity.

The respiratory system bears the chief brunt of the attack. The mucosa of the air passages is bright red, swollen, and covered with sero-purulent secretion. The lymph glands are enlarged. In most cases there is catarrhal pneumonia. In fatal cases the pleura is often found covered with fibrinous exudation; there may be fluid in the pericardial cavity and fatty degeneration of the heart. Liver and kidneys show fatty or parenchymatous degeneration, and there may be myelitis. Intense catarrh of the conjunctiva may lead on to ulcerative keratitis. The familiar symptoms are lassitude, loss of appetite, shivering, a dry nose, scanty urine, thin watery discharge from nose and eyes, dry husky cough, and sneezing. Discharge from nose and eyes becomes purulent, obstructing the nostrils and gluing the eyelids together. There is rapid emaciation and loss of strength. The initial exanthem may recur in severer form along with diarrhœa and icterus. When broncho-pneumonia sets in there is the characteristic offensive odour from the body.

Treatment consists in catching the disease in its early stages and raising the patient's resistance to invading organisms. To eliminate toxins, evacuants and diuretics are generally given. Intestinal antiseptics, such as hyposulphite of soda in full doses, have been found useful. The efficacy of canine distemper vaccine is in doubt; if used it must be given early. Many veterinary surgeons consider it useless except as a prophylactic. Apart from this, warmth, quiet, and frequent small easily-digested meals are the chief means of preventing chorea and the other troublesome nervous sequelæ. Donovan's solution has some reputation as a tonic in convalescence. Isolation should be strictly enforced, with sterilisation of feeding utensils and precautions against carrying infection on the part of the attendant.

FRAUDULENT "CURES."

A TRIAL held recently in the department of the Seine, as a result of which a chemist and a pharmacist were condemned to a month's imprisonment and a fine of Fr.5000, has aroused interest afresh in the subject of fraudulent remedies. In this case the tribunal considered the advertisement and sale of "toxicurol," a tuberculosis "cure," as illegal practice of medicine, and though the defendants' action was described as bordering on swindling, they could not be punished as swindlers, it seems, because no third party was associated in the enterprise. If one or more medical men had been found associated in this fraud, as was the case in the MacLaughlin belt trial in Paris (June 7th, 1912) that would have constituted a third party and made the case one of fraud. Mr. A. Peytel, writing in the *Paris Médical* for August 20th, suggests that the crime should be made one of fraud even without the intervention of a medical accomplice. This seems a logical conclusion and would provide the law with a powerful weapon for good. Reference of vaunted cures to an expert commission should then be made obligatory whenever a complaint is placed by responsible people—by the medical associations, for example.

Every country suffers from the curse of secret remedies. In the *Scalpel* for Oct. 15th Dr. Van Langendonck has accumulated evidence of some shocking examples from advertisements in the Belgian press. Remedies for "disorders in women," discovered by ecclesiastical worthies in the seventeenth century, are bad enough, but one may share fully the writer's indignation at an advertisement (from *Le Soir*) which runs, "*Le cancer.* Le cancer guéri rapidement et radicalement par le remède célèbre du curé Daury, ..." and at a pharmacist who promises to cure gonorrhœa in a fortnight with a dry remedy or to send the complete treatment of syphilis in return for Fr.10.60. Such advertisements offend against society and should be severely punishable.

PUBLIC HEALTH IN NYASALAND.

ON March 31st, 1920, the estimated European population of this Protectorate, including Government officials, was 729 males and 286 females—a total of 1015, as compared with 724 in the previous year. The Asiatic population increased by 108 to 515 during the year. The native population, which is estimated on the number of huts, was put down at 545,000 males and 658,000 females—total 1,203,000. During the year 170 European officials received medical treatment; 20 were invalided, but there were no deaths. A total of 313 non-official Europeans came under treatment, of whom seven died. The shortage of medical staff rendered it impossible to carry out any special investigations in connexion with communicable diseases, except that investigations were continued in the North Nyasa district in the matter of plague. The only recorded cases occurred in August. As statistics have shown that infection with this disease reaches its height in the rainy season, it is a matter for congratulation that no cases at all occurred from August, 1919, to the end of March, 1920—i.e., throughout a whole wet season. From April to December the preventive measures were continually enforced, and during that period a total of 1,247,068 rats were killed. The year 1910–20 may be regarded (says the writer of the annual report) as confirming the belief that the prosperity which awaited the future progress of this Protectorate at the conclusion of hostilities is likely to be maintained. It is now apparent that the war has had no permanent ill-effect on the prospects of the country; and when once the native character reverts to its normal condition, and the general conditions of trade recover from their present stagnant state, it is confidently to be expected that Nyasaland will take an ever increasingly important place in the Empire.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Nov. 15th.

GENERAL MEETING OF FELLOWS: at 5 P.M.
Ballot for Election to the Fellowship. (Names already circulated.)

Wednesday, Nov. 23rd.

OCCASIONAL LECTURE: at 5 P.M.
Dr. Gustave Monod: Syphilis of the Stomach. A Discussion will follow in which it is hoped the following will take part: Dr. Charles Bolton, Dr. A. F. Hurst, Dr. J. W. McNee, Sir Berkeley Moynihan, Mr. Herbert Paterson, Mr. J. Sherren, and Mr. A. J. Walton. There will also be an Exhibition of Rare Specimens.

MEETINGS OF SECTIONS.

Monday, Nov. 14th.

WAR: at 5.30 P.M.
Dr. W. Wallace: *An Epidiascopic Demonstration of War Injuries on the Fundus of the Eye.*

Tuesday, Nov. 15th.

PATHOLOGY: at 8.30 P.M.
Dr. W. E. Gye and Dr. W. J. Purdey: The Poisonous Properties of *Colloidal Silica*.
Mr. A. T. Glenny and Miss Allen: A Guinea-pig Epizootic Associated with Dietary "Deficiency."
Professor F. Hobday: Cleft Palate in Animals, with Specimens and Illustrations.
Mr. J. B. Buxton and Mr. A. T. Glenny: Active Immunisation against Tetanus in Horses with Toxin-antitoxin Mixtures.
Dr. H. J. Sudmersen and Dr. Eagleton: Standardisation of Dysentery Serum, Protective and Agglutinating Antibodies.

Wednesday, Nov. 16th.

HISTORY OF MEDICINE: at 5 P.M.
At the Historical Medical Museum, 51a, Wigmore-street, W.
Papers: Dr. Charles Singer (President): Demonstration of Museum Specimens, illustrating Ancient Greek Medicine.
Dr. M. B. Ray: Egyptian Deities associated with Healing.

TROPICAL DISEASES AND PARASITOLOGY: at 8.30 P.M.
(1) A description of the Oöcysts of *Eimeria Oxyspora* Dobell, 1919, with clinical notes of a new case: *Embadomonas intestinalis* (Wenyon and O'Connor) 1917; description of the cysts and *free forms* with clinical notes of a new case: by Dr. W. Broughton Alcock and Dr. J. Gordon Thomson.
(2) *A demonstration and notes on Helminth*: by Prof. R. T. Leiper, Dr. M. Khalil, and Mrs. Philpots, M.Sc.

Thursday, Nov. 17th.

DERMATOLOGY: *at 5 P.M. (Cases at 4.30 P.M.)*
Cases will be shown.

Friday, Nov. 18th.

OTOLOGY: at 5 P.M. (Cases at 4.45 P.M.)
Cases will be shown by Dr. Dan McKenzie, Mr. Sydney Scott, and others.
Communications by Mr. Sydney Scott and Mr. E. D. D. Davis.
Short Papers by Dr. A. A. Gray (with Lantern-slide Demonstration) and by Mr. A. R. Tweedie.

ELECTRO-THERAPEUTICS: at 8.30 P.M.
Dr. Frans Daels (of Ghent): (1) Histological Pictures of the Curing of Uterine Baso-cellular Epithelioma (with micro-photos). (2) The Irradiation of the True Pelvis with the Help of Drainage Tubes (with Diagrams).
Dr. G. Fildes: Further Remarks on the Potter-Bucky Diaphragm.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
MONDAY, Nov. 14th.—8 P.M. Clinical Evening. Cases will be exhibited by the following:—Mr. James Berry, *Sir John Broadbent, Sir William Willcox*, Dr. F. J. Poynton, Mr. Donald Armour, Mr. T. P. Legg, Mr. Herbert W. Carson, Dr. C. E. Lakin, Mr. Z. Cope, *Dr. T. Izod Bennett.* Cases will be exhibited from 8 to 9 P.M., after which a Discussion will take place.

LONDON DERMATOLOGICAL SOCIETY, 49, Leicester-sq.
TUESDAY, Nov. 15th.—4.30 P.M., Agenda: Pathological Specimens, and Cases sent for Consultation. Clinical Cases. Dr. J. L. Bunch: Lupus Erythematosus, Syphilis. Dr. W. Griffith: Diffuse *Scleroderma*, Acute Cutaneous Syphilide. Dr. M. G. Hannay: Granuloma Annulare. Dr. E. J. D. Mitchell: Syphilis. Dr. S. R. Kapoor: Pityriasis Rubra Pilaris. Dr. W. K. Sibley: Lupus Erythematosus.

MEDICO-LEGAL SOCIETY, 11, *Chandos-st.*, Cavendish-sq., W.
TUESDAY, Nov. 15th.—8.30 P.M. Paper:—Dr. T. Good: Nature *versus* Law, with special reference to the Development of Psychotherapy and its Problematical Use in the Treatment of Feeble-minded Persons and Criminals *(followed by Discussion)*.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.
THURSDAY, Nov. 17th.—8.15 P.M. *A Laboratory Meeting will be held at the London School of Tropical Medicine. Endsleigh-gardens, N.W.* Dr. Broughton-Alcock, Dr. J. G. Thomson, Colonel A. Alcock, Dr. P. Manson-Bahr, Prof. R. Leiper, Major H. C. Brown, Dr. A. C. Stevenson, Dr. S. H. Daukes, Dr. C. Morley Wenyon, *and others will give Demonstrations.*

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
The Annual General Meeting of the Fellows and Members *will take place at the College on* Thursday, Nov. 17th, at 3 P.M.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, Nov. 14th.—12.15 P.M., Dr. Burnford: Pathological Demonstration. 2 P.M., Mr. *Addison*: Visit to Surgical Wards. Dr. Scott Pinchin: Medical Out-patients. Dr. Simson: Diseases of Women. 2.30 P.M., Dr. Arthur Saunders: Visit to Medical Wards. 5 P.M., Mr. Donald Armour: *Practical Surgery* (Lecture V.).
TUESDAY.—11 A.M., Dr. McDougal: Electrical Department. 12 noon: Mr. Sinclair: Appendicitis (Lecture). 2 P.M., Dr. Burrell: Medical Out-patients. Dr. Pernet: Skin Department. *Dr. Morton*: X Ray Department. 2.30 P.M., Mr. Tyrrell Gray: Demonstration of Cases (Surgical Wards). 5 P.M., Mr. Banks Davis: Nasal Catarrh (Lecture).
WEDNESDAY.—11 A.M., Mr. MacDonald: *Demonstration* of Cystoscopy. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Tyrrell Gray: *Operations*. Mr. Gibb: *Eye Department*. *Dr. Burnford*: Visit to Medical Wards. 5 P.M., Mr. Donald Armour: Practical Surgery (Lecture VI.).
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 12 noon, Dr. Scott Pinchin: Diseases of the Heart (Lecture). 2 P.M., Mr. MacDonald: Surgical Out-patients. 5 P.M., Dr. Simson: Modern Developments in the Management of Labour (Lecture I.).
FRIDAY.—10 A.M., Dr. Robinson: *Gynæcological* Operations and Visit to Wards. Mr. Dudley Buxton: Dental Department. 2 P.M., Mr. Sinclair: Surgical Out-patients. Mr. Banks Davis: Diseases of the Throat, Nose and Ear. Mr. Addison: *Operations*. 2.30 P.M., Dr. Pritchard: Demonstration of Cases (Medical Wards). 5 P.M., Dr. Burrell: Sanatorium Treatment.
SATURDAY.—10 A.M., Dr. Arthur Saunders: Medical Diseases of Children. Mr. Simmonds: Orthopædic Department. 2 P.M., Dr. Owen: Medical Out-patients.
Daily:—10 A.M., Visit of Post-Graduates to Wards. 2 P.M., In-patient, Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
MONDAY, Nov. 14th.—10 A.M., Mr. W. E. Tanner: Surgical Out-patients. 2.30 P.M., Dr. A. J. Whiting: *Demonstration* in Medical Wards. Mr. E. Gillespie: Surgical Operations. Dr. J. B. Alexander: Medical Out-patient. Mr. *J. Bright Banister*: *Gynæcological* Out-patients. Dr. Shanks: X Ray Department. 4.30 P.M., Mr. J. Bright Banister: The Toxæmias of Pregnancy. 7 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.
TUESDAY.—9.45 A.M., Lt.-Col. R. H. Elliot: Eye Cases and Operations. 2 P.M., Mr. J. Howell Evans: Surgical Out-patients. 2.30 P.M., Mr. H. W. Carson: Surgical *Operations*. Mr. C. H. Hayton: Throat, Nose and Ear Out-patients. Dr. J. Metcalfe: X Ray Department. Dr. L. Yealland: Medical In-patients. 3 P.M., Mr. J. Howell Evans: *Surgical In-patients.*
WEDNESDAY.—2 P.M., Mr. C. H. Hayton: Throat Operations. 2.30 P.M., Dr. J. B. Alexander: Medical Out-patients. Dr. W. Jenkins Oliver: Skin Cases. 6 P.M., *Dr. F. L. Provis and Mr. T. H. C. Benians*: Venereal Department.
THURSDAY.—2.30 P.M., Mr. J. Bright Banister: Gynæcological Operations. Dr. A. J. Whiting: Medical Out-patients. Mr. H. W. Carson: Surgical Out-patients. Dr. J. Metcalfe: X Ray Department. Mr. N. F. Fleming: Eye Out-patients.
FRIDAY.—2 P.M., Mr. J. Howell Evans: Surgical Operations. 2.30 P.M., Dr. C. E. Sundell: Children Out-patients. Mr. E. Gillespie: Surgical Out-patients. Dr. Shanks: X Ray Department. 4.30 P.M., Mr. E. Gillespie: *The Treatment of Paralysis by* Orthopædic Methods. 5 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.
SATURDAY.—10.30 A.M., Mr. W. E. Tanner: Surgical *Operations*. 3 P.M., *Mr. H. W. Carson*: Visit to Surgical Wards.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, Marylebone, W.
MONDAY, Nov. 14th.—11 A.M., Dr. Goodall: Out-patients. 2 P.M., Dr. Moon: In-patients. 5.30 P.M., Lecture:—Dr. Price: Depressed Conductivity: Heart Block.
TUESDAY.—10 A.M., Dr. Parsons-Smith: *Out-patients*. 10 A.M., Dr. Price: In-patients. 2 P.M., Sir S. Russell-Wells: Out-patients.

could hardly be accepted. It was more plausible that the salt solutions used caused a swelling which a number of the blood corpuscles could not withstand without losing their colouring matter. If this assumption were true, then it would follow that the serum of blood could also be diluted with water without the occurrence of hæmolysis. This, indeed, proved to be the case. The serum of animals could be diluted with percentages of water up to multiples of ten, that of man with 50 per cent. and more before colouring matter was discharged, and the conclusion was that a diluted serum which just caused hæmolysis to set in was isotonic with a salt solution which could do the same. A simple calculation now showed that the blood serum of the majority of warm-blooded animals, including man, was isotonic with a NaCl solution of 0·9 per cent., and not of 0·6 per cent., as was generally thought at the time, and which had always been called the physiological NaCl solution. In connexion with this I therefore introduced the terms *hyperisotonic* and *hypoisotonic*, according as the solutions had respectively a stronger or weaker power of attracting water than normal serum. All this was proved by determination first of the corpuscular volume[6] and afterwards of the freezing-point. I, and after me Hedin[7] and others, found that the blood corpuscles shrink in hypertonic and swell in hypotonic solutions. I considered, and so did they, that the blood corpuscles, like the plant cells of de Vries, were semi-permeable, and thus allowed only water to pass through.

II. PERMEABILITY OF RED CORPUSCLES TO ELECTROLYTES (ANIONS AND KATIONS).

Experiments by quantitative chemical methods in 1889[1] convinced me quite unexpectedly, however, that this was not the case—in other words, the blood corpuscles were not semi-permeable. For when they were mixed with a salt solution which was isotonic with the serum their volume, it is true, remained unchanged, but they lost chlorine, and, as I was able to demonstrate afterwards, an interchange took place between the contents of the red corpuscles and their environment. The elimination of chlorine was especially studied. Through these researches the question of permeability was introduced for the first time, and since then permeability has been a prominent item on the programme of large numbers of physiological inquiries. When we come to think of it, it is somewhat remarkable that it had not been earlier realised that permeability to dissolved substances is necessary for the life of cells, whether for the assimilation of nutritive substances or for the elimination of waste products. Yet it was only with difficulty that we succeeded even in recent times in getting the idea of permeability, to inorganic substances for instance, universally accepted.*

After the permeability of blood corpuscles to chlorine was established in 1889 I was able in 1892[9] to offer additional proofs. I inquired whether, seeing that the hæmolysis of the red corpuscles is so sensible to slight modifications in the concentration of the surrounding fluid, the erythrocytes of the arterial and venous blood of the same animal would show any difference in respect to the salt concentration at which colouring matter was discharged. Such a difference proved to exist; the carotid blood of a horse showed commencement of hæmolysis in a NaCl solution of 0·61 per cent., the jugular blood, on the other hand, had already hæmolysed in a NaCl solution of 0·62 per cent. This fact was the starting-point of a new series of investigations on permeability. On the assumption that this phenomenon was in some way connected with the carbon dioxide concentration, we investigated the influence of CO_2 on the loss of colouring matter. This influence proved to be very great, and led to the study of the influence of carbon dioxide on the distribution of the constituents of the blood between corpuscles and serum. In the first place, it appeared that when blood was treated with a quantity of carbon dioxide, which was well within physiological limits, an interchange of constituents took place between blood corpuscles and blood serum. If the carbon dioxide was driven out the original partition was fully restored; the phenomenon was a reversible one, and the conclusion was drawn that it must be of importance to life. For while the blood flows through the capillaries of the tissues it is acted upon by carbon dioxide, and when it reaches the lungs the carbon dioxide is expelled again. Of the changes which carbon dioxide brings about in the distribution of the blood constituents between the blood corpuscles and serum the most important was a transit of chlorine into the corpuscles and an increase of alkalinity—that is, in the amount of diffusible alkali of the blood serum.† There was also a considerable swelling of the blood corpuscles. With every act of respiration, therefore, rhythmical changes take place; while the blood circulates through the tissues the blood serum becomes more alkaline, poorer in chlorine and phosphoric acid, and poorer in water. Owing to the latter the concentration of albumin and other organic substances in the plasma increases. When the blood reaches the lungs again the carbon dioxide is expelled and the partition of the constituents is as before. These results can be confirmed by comparative experiments on normal carotid and jugular blood. It would carry me too far if I were to enter upon the significance of these phenomena in metabolism. It is obvious that in venous congestion the interchange between blood corpuscles and plasma is much more pronounced than in the normal circulation.

These various facts about CO_2 were useful to British and American investigators during the war. It may be observed that they have also formed the basis for the well-known researches of Korányi on the diagnosis and treatment of heart diseases.[11] This investigator has shown how an uncompensated heart disease can be differentiated from renal insufficiency. In both cases the lowering of the freezing-point of the blood serum is increased, in the case of the heart disease through the accumulation of carbon dioxide, and in the case of renal insufficiency through the accumulation of waste products. In both cases a decrease in the amount of chlorine in the blood plasma is observed. To distinguish between these two diseases Korányi suggested that oxygen should be passed through the blood drawn from the patient. If it is a case of uncompensated heart disease, then there is an increase of chlorine, and also the freezing-point of the serum becomes normal again. If these phenomena are absent then the diagnosis is renal insufficiency. Korányi also worked on the same lines in the therapeutic direction. In cases of uncompensated heart disease he administers oxygen: the surplus of carbon dioxide disappears, and with it the cyanosis. The blood undergoes the same changes which are observed in vitro when oxygen is passed through; thus the blood corpuscles surrender water to the plasma, with the result that the percentage of chlorine increases. It is obvious that in consequence of this dilution of the plasma with water the viscosity of the blood will diminish and the circulation be improved. This improvement of the circulation serves a double purpose: firstly, the blood of the coronary system will feed the heart better than when the flow of blood is slow on account of the great viscosity of the plasma. The improvement in the circulation is shown by the kidney function. The diuresis increases, and this is further facilitated by the increased amount of chlorides in the plasma. The special value of the oxygen inhalation is seen in the fact that through the improved action of the

---

* It may be remarked en passant that in the literature one repeatedly comes across the idea that the question of permeability originated in the lipoid-theory of Meyer-Overton.[8] This theory, however, only appeared in 1899, ten years later, and its sole object was the study of the conditions under which organic substances could penetrate the wall of the cell. According to that theory, as you know, this penetration is considered be subject to the solubility of the substance which is experi-ated with in the lipoid cell-surface.

† An increase of the amount of alkali in the serum had been already seen by Zuntz[12] in *saturating* blood with CO_2.

Notes, Short Comments, and Answers to Correspondents.

GASTRIC RESPONSE TO FOODS.

The subject of gastric response to foods is being investigated in the Jefferson College of Philadelphia jointly by several observers, including R. J. Miller, O. Berheim, R. E. Martin, and P. B. Hawk, and their results are published in the *American Journal of Physiology*, Vols. LII. and LIII. The psychic secretion of gastric juice in normal men forms part of the series. It is easy to make the mouth water, and no one who has ever read Elia's "Dissertation Upon Roast Pig" can ever forget Lamb's inimitable description of the first accident of the kind that befel Bo-bo, son of the swineherd Ho-ti, when he smelt the smell of roast pig—when an odour assailed his nostrils, unlike any scent which he had before experienced. A premonitory moistening at the same time overflowed his nether lip. He did not know what to think. He ate crackling for the first time, discovered that roast pig tasted delicious, and surrendered himself up to the new-born pleasure. Nor must we forget to record the tickling pleasure which the graceless whelp Bo-bo experienced in his lower regions. But there are other psychic secretions besides those of the salivary and lachrymal glands. A well-set-out table, bedecked for dinner with properly and tastily cooked viands, causes a secretion of gastric juice, whilst unappetising food excites no response. Tasting or chewing alone is not effective without the scent or sight of food. Even the thought of a luscious grilled beefsteak excites marked secretion of gastric juice, which may be arrested by disagreeable odours. Chinese-preserved eggs with their, to us, repulsive and disagreeable smell and taste, delay the acid-formation and prolong the time of emptying of the stomach. Reading a newspaper at a meal does not seem to change the gastric secretion, but, on the other hand, mental irritation and worry have a distinct influence thereon. The effect of water, tea, coffee, and cocoa on the digestion of a meal consisting of beefsteak, mashed potatoes, toast and butter was studied, the acidity and the time the food remained in the stomach being noted. The latter was scarcely altered after drinking a litre of cold water, cold or hot tea, hot coffee, pure, with cream, or with cream and sugar. Much sugar added to coffee delays the emptying of the stomach. Water, tea (hot or cold), hot coffee with or without milk, or cocoa in quantities of about a litre diminish the acid formation as compared with a meal without the addition of fluid, while a litre of tea or coffee increases the heart beat and pulse considerably, causes a fall of blood pressure and certain nervous symptoms. Cocoa does not cause these symptoms, but leads to a feeling of distension or fullness of the stomach. The amount of urine excreted 90 minutes after taking tea or coffee was 550–860 c.cm. and after cocoa 125–372 c.cm.

The response of the human stomach to pies, cakes, and 50 different varieties of puddings was also studied. The stomach is emptied on the average 2 hours 18 minutes after partaking of pudding, 2 hours 27 minutes after pies, and 3 hours 2 minutes after cakes. Meat pies leave the stomach after 2¾–3¼ hours, the fruit variety after a shorter period. The crust of the pie lingers longer in the stomach than do the contents of the pie, but the mode of preparation of the crust plays an important part. Puddings to which gelatin is added leave the stomach very quickly, exciting a small acid-formation, while puddings rich in proteins (bread pudding) give a higher acid value. As to sugar, candies, and other sweetmeats, large doses (100 g.) of cane or grape sugar in concentrated solution diminish considerably the gastric secretion and delay emptying of the stomach, whilst small doses (10 g.) seem to have no action. Sweetmeats diminish the secretion and delay the emptying of the stomach, and this to a greater or less extent according to their sugar content. The result is affected by the presence of aromatic substances, and especially by the addition of milk, eggs, or chocolate, which excite the gastric secretion. Sweetmeats should thus never be eaten before a meal.

BABY MANAGEMENT.

A NEW book on the management of the baby during its first year needs to be exceptionally good to justify its appearance in the present day when such books abound. The small pamphlet by Mrs. J. Langton Hewer, which has just been published,[1] entitled "The Baby of To-day," may fairly claim a place among these on the score of merit, the teaching being throughout consistently sound and practical. The 24 pages contain most of the essential points in the management of infants, including hints on nursing, food, clothing, cleanliness, sleep, exercise, the formation of good habits, and general training, the whole forming a useful guide to nurses and baby-minders in general, while its moderate price brings it within the reach of all. The pamphlet deserves a wide circulation.

A REGISTER OF MASSEUSES AND MASSEURS.

The Chartered Society of Massage and Medical Gymnastics has issued a register (St. Clement's Press, Ltd., price 3*s.* 6*d.*) of its members which will appeal to medical men who wish to prescribe massage, medical gymnastics, or medical electricity for their patients and have no personal knowledge of persons competent to administer such treatment. The register consists of an alphabetical list (91 pages) of masseuses, with addresses and any additional qualifications registered, followed by a similar list (7 pages) of masseurs. The concluding 31 pages are devoted to a place-index which will be found extremely useful.

FOOD VALUE OF WHITE FLOUR.

A MEMORIAL is being organised by the Bread and Food Reform League to the Minister of Health suggesting that the food leaflet to be published by the Ministry should make direct reference to the mineral content of oatmeal and whole-wheatmeal, the necessity of grinding them in a digestible form, and the importance of the germ being retained in household bread. The memorial has already been signed by a number of influential members of the medical profession and scientific societies.

SEVEN AT A BIRTH.

Some notes on Lagos in a recent issue of *Man*, the journal of the Royal Anthropological Institute of Great Britain and Ireland, by Mr. N. W. Thomas, state that the first born of twins is called *Taiwo* (see the world), the second *Koindi* (come behind), because it is supposed to send the other on in front to see the world. The *Koindi*, it is said, usually dies, and in that case an image of it must be made or the mother will not bear any more children. In the case of triplets, the third one is called *Idowu* (the servant of twins). The next child is called *Alaba*, and is the servant of *Idowu*, and the next is *Idogbe*, who watches the house while others come, and is very precious. Seven are said to have been born at once in Ibadan in 1907; an eyewitness certified this fact to Mr. Thomas, who comments: "In view of the case of six at a birth on the Gold Coast, attested by an English medical man, there seems no reason to doubt the story."

THE DISTRIBUTION OF MOSQUITOES IN ENGLAND.

The Mosquito Investigation Committee of the South-Eastern Union of Scientific Societies have issued another circular (No. 5) in connexion with their inquiry into the distribution, habits, and breeding places of *A. plumbeus*. Two reports have been submitted to the Ministry of Health since the issue of circular No. 4 in September, 1920. The researches following this circular established the fact that *A. plumbeus* is found extensively distributed throughout the South-Eastern area of England. In some districts all stages have been found; in others only larvæ and imagines. The species hibernates as partly grown larvæ, mainly in beech, birch, chestnut, and holly tree-holes, and imagines have been found in every season of the year except winter. The Minister of Health, in acknowledging the committee's second report for the half year ending June 30th, 1921, desired the inquiry to be continued and a further report to be submitted with special reference to any curtailment of distribution or decrease in numbers of the species that may have been caused by the severe drought of the past summer. A questionnaire designed to elicit further information forms the substance of circular No. 5. Further information on the important work done by this committee may be obtained from the hon. secretary, Rev. T. W. Oswald Hicks, "Lesware," Linden-road, West Green, London, N.

Those who are interested in but have as yet no knowledge of entomology will find a popular introduction to this subject in *British Insect Life*,[1] by Edward Step, F.L.S., a book written with the object of interesting non-scientific readers in the several types of insect life commonly met with in this country. It is illustrated with reproductions of photographs which give a fairly clear idea of the appearance of the insects; a good coloured frontispiece shows the meadow brown butterfly. It is, of course, impossible in a book of this scope to deal with all the species of known British insects, of which there are some 12,000, but the author has described typical examples with a minimum of technical language. Members of the public who learn to identify some of the disease-causing agents, and are prepared to make observations on their habits and breeding-places, are taking an active and useful part in forwarding the preventive side of medicine.

injection of foreign blood corpuscles, of complement-fixation, hæmolysis, agglutination, and so many other things? But also vice versa, and this is worth repeating, the study of the osmotic relationship of the erythrocytes was indispensable for the correct application of red corpuscles in the researches on immunity. It is owing to the above-mentioned advantages of the red corpuscles that the results obtained with them have repeatedly been the guides to important researches on cells and tissues which can only with difficulty be examined. We can also mention other cells which have the same advantages as the red corpuscles—namely, the white corpuscles; for these also are cells which can be easily examined in an isolated condition in their natural environment. But outside my laboratory they have, unfortunately, scarcely been examined as to their permeability. This is the more unfortunate because in the phagocytic power one has an excellent means of making accurate quantitative observations on life, or rather on one of the vital attributes of life, after the equilibrium has been disturbed by the addition of definite substances to the medium. I have outlined in a monograph (1912) some of the interesting results which can be obtained from a study of these cells.[21]

Of the isolated cells, which have been examined by me in a manner similar to that used for the red corpuscles on their osmotic behaviour towards salt solutions, can be mentioned spermatozoa, lymph gland and epithelial cells, the parenchymous cells of the liver, spleen and kidney, and also the nuclei of all these cells, but I cannot expatiate here on these.

I will now go over the question as to whether the permeability is constant for one and the same kind of cell.

V. THE PERMEABILITY CHANGES (VITAL PERMEABILITY).

It is now some 20 years since I pointed out for the first time that the permeability of one and the same kind of cell has no constant value, but is dependent on the physiological conditions of these cells.[1]

1. *Influence of CO_2, Acids, and Alkalies on Red Corpuscles.*—As already mentioned, I stated in 1892 that the permeability of red and white corpuscles changes quantitatively in a rhythmic way with every act of respiration. Snapper also demonstrated (1912)[25] in my laboratory by purely chemical experiments that the permeability of red corpuscles is changed by the influence of traces of sulphuric acid, and also in diseases, accompanied by fever, especially in pneumonia.

2. *Influence of $MgSO_4$ on Intestinal Epithelium.*—Further, in 1898,[26] I was able to show that intestinal epithelium with great difficulty allowed of the passage of common salt after it had been in contact with a solution of magnesium sulphate.

3. *Experiments on Permeability of Glomerular Membrane to Glucose.*—These experiments demonstrated the variable permeability to inorganic substances. Of late years, however, experiments have been performed in my laboratory with organic substances, more especially with glucose and its isomers and stereo-isomers. These experiments chiefly dealt with the permeability of the glomerular epithelium to these substances and the profound influence which is exercised on it by very minute physiological changes in the liquid flowing through the glomerular capillaries. I shall try to deal with the subject in a chronological order.[27] Since the time of Claude Bernard it has been known that though sugar is never absent from the blood it rarely appears in the urine of normal individuals. What is the cause of this, and why does sugar not appear in the urine until its amount in the blood exceeds a certain limit? Several possibilities have been considered. I shall not dwell on these; I only wish to point out that discussions on these possibilities have not reckoned with the fundamental question whether the kidney allows free glucose to pass through or not. Experiments were made with perfused kidneys; to ensure that the perfusing liquid contained sugar exclusively free and not as a colloidal compound a Ringer's solution containing sugar was taken. If the concentration of sugar in the artificial urine formed was the same as that of the original perfusing liquid the conclusion could be drawn that the kidney is permeable to glucose. After this it could be determined whether addition of serum causes a retention of sugar. Should this be the case, it would be practically certain that there is present in the serum a substance which binds the sugar in a form that the glomerular epithelium does not allow to pass through, and eventually it could be investigated what the substance in the serum is. With these investigations Dr. R. Brinkman and I have kept ourselves busy for more than two years; through them we have come to the most unexpected results, which now and then led us into side-tracks which were important in themselves.

Frogs were exclusively used for the experiments; the kidneys were perfused through the aorta at a pressure up to 60 cm. with Ringer's solution ($NaCl$ 0·6 per cent., KCl 0·01 per cent., $NaHCO_3$ 0·02 per cent., and $CaCl_2$ 0·02 per cent.) containing 0·05 per cent. of glucose. Approximately 150 c.cm. passed through the kidneys per hour.

The urine is formed in the glomeruli. To grasp this a knowledge of the circulation in the frog is needed; in contrast to what we find in warm-blooded animals, the renal arteries supply the glomeruli, and to a very small extent the tubules, which get their blood-supply almost wholly from the renal portal vein which carries off the greater part of the blood from the hindquarters. It now appears that if a liquid is made to flow through this latter vessel under a pressure of 60 cm. not a drop of urine is excreted. Excretion takes place only under a much higher pressure, and even then very slowly. It is therefore clear that in our experiments, where the liquid flows through the renal arteries, the urine is derived from the glomeruli.

The fact that it is possible thus functionally to separate the contents of the glomeruli and the tubes so well from each other makes the frog an admirable object for the study of the formation of the urine, and British authors are very well acquainted with this fact. In our earlier experiments the percentage of glucose in the urine and the perfusion liquid was always the same. These results were also obtained after ligature of the renal portal vein. It was therefore obvious that the urine obtained was a purely glomerular filtrate so far as glucose was concerned, and that the glomerular membrane was permeable to glucose.

But further experiments made it doubtful whether the usual Ringer's fluid was the physiological one for the perfusion of the kidneys. Systematic changes in the fluid taught us that for the permeability of the glomerular membrane the concentration of the free calcium-ions and of $NaHCO_3$ are factors of preponderant importance, and that in using the right concentrations the urine was free from sugar; in other words, the glomerular membrane now showed itself impermeable to physiological quantities of glucose. As regards the concentration of the $NaHCO_3$, its proportion in the usual Ringer's solution is too low. No glucose was retained in the absence of $NaHCO_3$. It is known that one function of $NaHCO_3$ is to preserve a certain alkalinity in the body fluids. The sodium phosphate and sodium protein also take part in this. In this connexion these substances are consequently called tampons, buffers, regulators, or moderators. Most investigators in their perfusion liquids use 0·02 per cent. $NaHCO_3$, but it appears to us that this concentration is too weak for perfusion through the frog's kidney, for if to the solution made up of $NaCl$ 0·6 per cent., $NaHCO_3$ 0·02 per cent., KCl 0·01 per cent., and $CaCl_2$ 0.0075 per cent. a little neutral red is added, then although the perfusion liquid is alkaline the urine becomes acid. The normal urine of the frog shows a weak alkaline reaction with neutral red. The buffer concentration of 0·02 per cent. was thus too weak to keep the urine reaction a weak alkaline one. But what is still more important, the retentive powers of the kidneys for sugar grow considerably weaker and finally disappear altogether. Clinicians will immediately think of the relation existing between acidosis and glycosuria.

We then determined the alkalinity of the frog's serum by titration with neutral red paper as indicator (Snapper). This corresponded to a $NaHCO_3$ solution of 0·285 per cent., and consequently a Ringer's solution was made with the following composition: $NaCl$ 0·5, KCl 0·01, $NaHCO_3$ 0·285, $CaCl_2$ 0·015 per cent. The urine now was perfectly free from sugar and was no longer acid. These results have been fully confirmed by Bahlmann (1920).[28] Hence the glomerular membrane has the power of retaining free glucose, and this power is governed by the chemical composition of the perfusion liquid, which cannot be that of

A Discourse

ON

PERMEABILITY IN PHYSIOLOGY AND PATHOLOGY.

Delivered at the University of London, under a Scheme for Exchange of Lectures in Medicine between England and Holland,

BY H. J. HAMBURGER, Sc.D., M.D., LL.D., F.R.S.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF GRONINGEN (HOLLAND).

I. INTRODUCTION: SOME HISTORICAL REMARKS.

THE problem of permeability plays a fundamental rôle in physiology as well as in pathology and pharmacology. For permeability means a power of admitting certain substances into the cell and of excluding others, and thus in physiology and pathology we endeavour to substitute for the mysterious principle of "conscious selection" of cells towards some substances, and for the so-called "vital activity," simple physical and chemical factors, no matter how complicated the coöperation of these factors may ultimately prove to be. This means also in pharmacology the finding of those forms of drugs which by penetrating into the interior of the cell are able to be of use there.

As an example, let us consider the acinus of the salivary gland. From the outside the epithelial cells are supplied with nutritive materials from the blood, while from the side next the lumen the saliva is secreted. The neo-vitalist has a simple explanation for this. According to him, the cells of the salivary glands take up, actively and selectively, substances from the blood, and secrete saliva through the so-called physiological motive force. If he introduces a salt solution into the alimentary canal, it is again the physiological vital force, an attribute of the living cell alone, that brings about the absorption. For, if the epithelium be injured by a poison, the process of absorption is entirely altered; this, he says, is because the dead epithelium lacks the physiological motive force. The same line of argument is sufficient for him to explain secretion and absorption in any part of the body. The neo-vitalist, it is true, freely acknowledges that physical factors also play a part in secretion and absorption, but the fundamental principle of these processes is a specific attribute of the living cell alone.

But what does this term "physiological motive force," so often used by Heidenhain, and by many after him, imply? Only this: we do not know and have to abide by that. It appears to me, however, that it is the duty of the biologist to endeavour at least to explain the phenomena along physical and chemical lines. Is it not probable that in the formation of saliva the cells by virtue of their properties of permeability allow the permeation of certain foodstuffs from the blood? That they convert these by chemical action and allow the products—namely, the saliva—to pass out at the other end, aided probably during this process by electrical currents, the cataphoresis? Such lines of thought appeal more to the modern physiologist than the idea that the cell, according to its needs, takes up actively, by virtue of a vital power, the necessary elements from the blood and discharge these into the lumen of the acinus. Some think that this physico-chemical explanation is much too simple and that the delicateness of the processes of life are thereby ignored. Yet upon more thorough investigation this proves not to be so, and one becomes more and more impressed by the marvellous intricacy and efficiency of these physico-chemical processes, while the number of unsolved questions continually increases.

I could add to these two examples, where permeability must play an important part, a great many others; but a detailed discussion would practically involve the whole of physiology. I shall be obliged, therefore, to limit my discussion to a few illustrative examples. In the choice of these I shall, while regardful of the *suum cuique*, also refer to my own work which, alas, has of late been too often overlooked. Who is there, however, of the senior among us who has no reason to complain of neglect? Moreover, these lectures are, I think, expected to have a personal flavour, and it is better so.

The study of the permeability of the animal cell may be said to have been introduced by researches which I carried out in 1889.[1] These investigations arose from my work in 1883 on the influence of salt solutions on the escape of colouring matter from the red blood corpuscles.[2] A year previously[3] (1882) the well-known botanist Hugo de Vries had conducted experiments upon the force with which plant cells attract water. He employed three biological methods, of which the plasmolytic gave the most reliable results. This method consisted in using a salt solution strong enough to bring about a slight separation of the contents of the plant cell from the cell membrane—in other words, to induce plasmolysis in the cell. This separation of the protoplast from the membrane (plasmolysis) was due to the fact that the water-attracting power of the surrounding fluid was something greater than that of the cell-contents. Hence de Vries concluded that solutions of any salts which caused the same degree of shrinkage when acting upon the same cell must have identical water-attracting powers. He called such solutions, having identical water-attracting powers, *isotonic* solutions; and the simple relations which appeared to exist between the concentrations of such solutions of different salts he named their isotonic coefficients. De Vries thus regarded the protoplast as semi-permeable—in other words, perfectly permeable to water but impermeable to substances dissolved in it. In the following year now (1883) I investigated the question whether the same phenomena which de Vries had observed in the plant cell applied also to the animal cell.[2]

I chose the red blood corpuscle as my material. The first step was to try to find a concentration capable of inducing plasmolysis in these cells. But I failed to find it. No plasmolysis could be observed in my experiments. Then I turned to the study of the escape of coloured matter from the red corpuscles. And so it was found that the red blood corpuscles were also subject to the law of isotonic coefficients. Between the concentration of salt solutions causing the escape of coloured matter from the same blood corpuscles the same numerical relation appeared to exist as between the concentration of salt solutions inducing plasmolysis in the same plant cell. These investigations on the blood corpuscles, as you no doubt recollect, marked the beginning of modern physico-chemical research in the medical sciences.

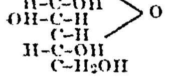
It may be observed in passing that it has repeatedly been stated that Van't Hoff's theory of osmotic pressure laid the foundation for these investigations on the blood corpuscles, but this is decidedly a mistake. The real basis for my work was given in de Vries's researches in plant physiology of 1882. These investigations and my own hæmatological researches furnished important data for an experimental proof of Van't Hoff's theory, which was based principally on thermodynamic considerations and on Pfeiffer's researches. Besides, Van't Hoff's theory was published for the first time two years later, in 1885,[4] and absolutely needed Arrhenius's theory of electrolytic dissociation (1887)[5] as a supplementary one to be accepted.

As already mentioned, I found that for every salt a concentration could be obtained in which the least resistant blood corpuscles lost their colouring matter, and in these concentrations the salts had the same power of attracting water. How could this phenomenon be explained? Could it be possible that these salt solutions, which had the same power of attracting water, brought about a slight shrinkage as in the case of the plasmolysis of plant cells? This

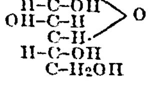
And it was found that the fructose passed through completely, likewise the mannose, while only part of the galactose was retained. You will notice how slight is the difference between the configurations of these five sugars, especially between d-glucose and its stereo-isomers galactose and mannose. Glucose, therefore, occupies a very peculiar place amongst the isomeric monosaccharides with regard to the glomerular membrane—that is to say, the glomerular epithelium distinguishes glucose from other sugars in a way which suggests the relation of sugars to ferments, like a lock and key. If we apply this to our case we would say that the key (glucose) does not fit the lock (glomerular membrane), and that the other sugars experimented with do fit and pass through. The power of the glomerular membrane to distinguish d-glucose from other sugars goes so far—and this is not without importance from a clinical point of view—that when d-glucose (dextrose) and lævulose are dissolved in the perfusion liquid the dextrose is still retained by the glomerular membrane, but the lævulose passes through. From this it is evident that the power of retention for dextrose is not quantitatively altered. The two sugars are separated from each other as by a filter. What is true for a mixture of dextrose and lævulose also applies to a mixture of glucose and lactose. The lactose passes completely into the urine and the glucose is retained just as when there is no lactose present.

These investigations form a new illustration for the law of stereo-isomerism, but here it is not of a chemical but of a physiological nature as they occur in the domain of permeability. We may repeat, therefore, that it is the configuration of the glucose molecule that imparts to this substance the peculiarity that causes it to be retained by the glomerular epithelium.

In order to know to what group of atoms the retention of glucose was due, we have examined other stereo-isomeric sugars, amongst which were pentoses, such as xylose, arabinose, &c., and some hexoses like galactose. Of these some passed through the glomerular membrane, others could only partially do so. Of those showing partial retention, we have examined especially d-galactose and l-xylose; the former has special importance as it is a constituent of the central nervous system. The partial retention, which was always of about 50 per cent. of the d-galactose and 25 per cent. of l-xylose, is very remarkable, because it appears to disagree with the idea of permeability. A mean between the two extremes of permeability and impermeability can hardly be conceived when we have to do with only a single substance. The reason for it lies in the fact that there are two modifications of d-galactose when dissolved in water—namely, the α and the β variety, which only differ in the attachment of the H and OH groups to the asymmetrical carbon atom, as shown by the graphic formula given below. The α variety is retained and the β variety allowed to pass through. The same is the case with l-xylose.



α-Galactose held back.

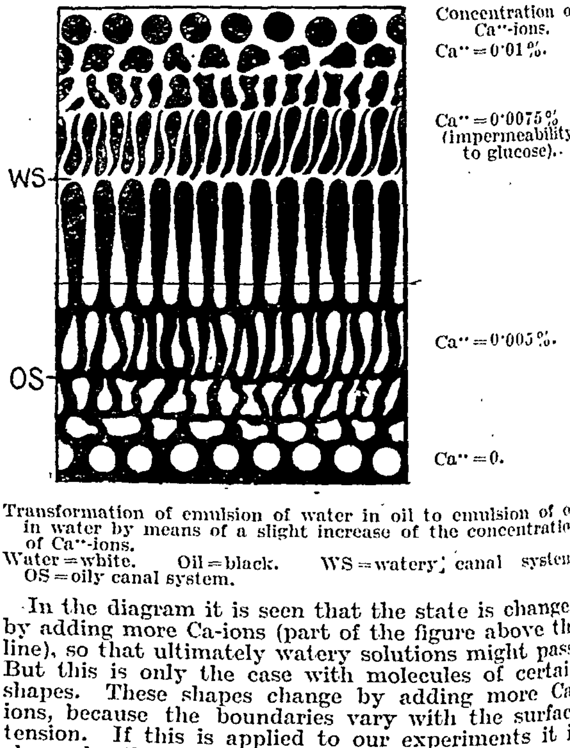


β-Galactose not held back.

To summarise, we may say that the cells, with hardly any exceptions, are permeable to ions of electrolytes and often to organic substances; further, that the physiological, or more generally the vital condition of the cell, or better the composition of the surrounding fluid, exerts a great influence on the permeability.

VI. Mechanism of Permeability.

There are two theories which can be used to explain permeability; the one is based on the polarised [illegible]tion of the surface of the cell, and this may be called the electrical theory; the other is the sieve theory. The first is embodied to a certain extent in Girard's scheme, which we have previously mentioned in connexion with the influence of acidity or alkalinity on the movement of ions. The second (sieve theory) is embodied in the views of Clowes.[38] It would take me too far to consider both these in detail, but I would like to make some remarks on Clowes's theory. This originated in an observation by Bancroft (1913),[39] that a mixture of oil and water can be emulsified permanently in two ways; the one emulsion consists of oildrops suspended in a continuous watery phase as in cream; the other consists of drops of water suspended in a continuous phase of oil as in butter. Clowes was able to convert an emulsion of the first kind into one of the second kind by simply shaking an emulsion of oil in sodium soap with a solution of calcium chloride. The reverse took place when shaking with sodium hydroxide. If this is applied to the protoplasm of cells one will obtain two different states of permeability on the addition of Na or of Ca; Ca causes an oily canal system and Na a watery canal system. From this it follows that Ca will create an impermeability to watery substances. In other words, as regards their effects on permeability Na and Ca are antagonistic to each other. The following somewhat modified scheme of Clowes illustrates the experiment very well.



Concentration of Ca··-ions.
Ca·· = 0·01 %.
Ca·· = 0·0075 % (impermeability to glucose).
WS
Ca·· = 0·005 %.
OS
Ca·· = 0.

Transformation of emulsion of water in oil to emulsion of oil in water by means of a slight increase of the concentration of Ca··-ions.
Water = white. Oil = black. WS = watery canal system. OS = oily canal system.

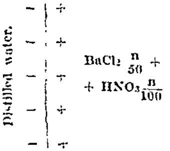
In the diagram it is seen that the state is changed by adding more Ca-ions (part of the figure above the line), so that ultimately watery solutions might pass. But this is only the case with molecules of certain shapes. These shapes change by adding more Ca-ions, because the boundaries vary with the surface tension. If this is applied to our experiments it is clear why the glomerular membrane becomes impermeable to glucose with an efficient concentration of Ca-ions in the perfusion liquid. It may be stated here that something very similar is obtained in the hæmolysis of red corpuscles. Dr. Brinkman and Miss Van Dam have also observed a decided influence of the concentration of calcium-ions on gastric movements and gastric secretion when the vagus nerve is stimulated. We are not astonished at this when we come to think that, on stimulating a nerve, one has probably to do with the influence of the calcium-ions on the neuro-muscular junction, which is formed at the place where the nerve and the muscle meet.

Why the impermeability in the presence of a definite amount of Ca-ions in the fluid should be replaced by permeability again when there is a superabundance of Ca in the liquid we cannot now discuss. An analogue of such a contrast is seen in the recent heart and the increased diuresis the œdema disappears; *what is especially remarkable is that the beneficent after-effects of oxygen inhalation last for so long a time.* The recent researches of Yandell Henderson[12] on shock, acapnia, ether-anæsthesia, are also based upon my experiments on the interchange of substances between red corpuscles and the environment.

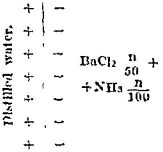
My experiments *on the effect of carbon dioxide on permeability* gave rise to the question whether the carbon dioxide as such or as an acid caused the interchange of constituents. The latter was *the case, because other acids also brought about the* same interchange, while addition of alkali to the blood had the reverse effect. Afterwards, in 1901, it appeared to me that we have here a general principle, for not only red corpuscles but also white blood corpuscles and other isolated cells suspended in their natural media showed a swelling in carbon dioxide and other acids and shrinking in traces of alkali;[13] also organs as a whole showed the same phenomenon. In this way a considerable swelling of the kidneys was demonstrated with the plethysmograph when a *trace of acid was added to the blood* and a shrinkage when the blood was treated with a little alkali.[14] In 1906 the Belgian physiologist Demoor obtained the same results.[15]

Although stress has been laid upon the permeability of the blood corpuscles to chlorine they appear to be permeable also to other acid radicals, as, for instance, to SO_4,[16] NO_3, and phosphoric acid. This can be demonstrated by quantitative chemical methods more clearly with blood corpuscles which have been treated with CO_2 than with arterial blood. I shall not dwell now upon the explanation of this fact. Only one remark. The objection has been made that the CO_2 had harmed the blood corpuscles so that they were no longer normal. This is not justified, however, because the amount of CO_2 which was added to the arterial blood was not necessarily beyond the physiological quantity, and, moreover, because the process was totally reversible.

Up till now we have considered the permeability of blood cells to Cl and other anions. Are they also permeable to kations—i.e., to metals? Investiga*tions made in our laboratory*[17] *afterwards proved* that, when a little water or a little salt is added to the serum there is also an interchange between the kations of the corpuscles and those of the surrounding fluid. Or, to put it generally, we observed that every disturbance of the osmotic chemical equilibrium causes an interchange of kations, as well as of anions between the blood corpuscles and their environment. The metals experimented with were Na, K and Ca. All these interchanges are intensified when CO_2 or other acids are added. Kœppe[18] and *myself*[19] *gave an explanation for these facts*, which has been almost universally accepted. I shall not dwell upon this question, but I only wish to draw attention here on the experiments of Girard[20] with simple membranes, which are very instructive.



Here 6 gr. ion Cl against 1 gr. ion Ba are diffused into the distilled water in 20 minutes.



Here only ½ gr. ion Cl against 1 gr. ion Ba are diffused into the distilled water in 20 minutes.

When a solution of barium chloride, mixed with a little *ammonia* or HNO_3, is subjected to diffusion against distilled water, the relative *quantities Cl and* Ba which pass through the polarised membrane during the same length of time are very different, as the above scheme shows.

Without polarisation of the membrane there had *to be a diffusion of 1 Ba against 2 Cl. Hence the* conclusion may be drawn how considerable must be the effect of hydrogen-ion concentration on the partition of the constituents of corpuscles and serum.

In cells the circumstances are more complicated than in the schema of Girard. I think here of the interchange in tissues between fixed cells and fluids which are in motion—e.g., here the principle of the initial rate of osmosis, studied by Lazarus Barlow[21]—is to be taken into account.

So far we have considered especially the perme*ability to salts and their components, the electrolytes.* Very likely the question may be put whether this can be justified and whether the electrolytes have indeed such a great significance. My answer to this is that, in the first place, the salts or their ions, by virtue of their water-attracting properties (osmotic pressure), exert an important effect on the passage of fluid between the cell and its surroundings; secondly, they strongly influence the state of colloid dispersion, and therefore the viscosity of fluids and cells. We recall here inter alia the influence of the *motility of the cell-contents on cell division* and fertilisation.

III. PERMEABILITY TO NON-ELECTROLYTES (ORGANIC SUBSTANCES).

Let me now direct attention to the organic substances. Gryns has divided organic substances into those that can enter blood corpuscles and those to which the blood corpuscles are impermeable.[22] According to him, they pass through if they cause hæmolysis when in isotonic concentration; if not they are held back. Such a representation of the matter was much too schematic, because several substances which thus appeared unable to pass through as a matter of fact did so, but only slowly. The permeability to organic substances has been investigated also by a method employed by Hedin to study the red corpuscles, and by Overton to study the cells of plants. On the whole there appears grosso mòdo to exist a correspondence between the permeability relationships of red corpuscles and those of plant cells; but Overton's idea, as stated in 1907,[23] *that all the known permeability relations of plant* cells can be applied equally well to animal cells and even to all animal cells is certainly wrong. To whom, in fact, will it be surprising, that, for example, a great number of organic substances which are able to pass through the intestinal epithelium are held back by the epithelium of the bladder? Indeed, the intestinal epithelium would poorly answer its purpose as an organ of absorption if it were impermeable, and the bladder epithelium would be a bad lining for a reservoir for metabolic waste products if it were to allow substances to pass through it. It is not at all immaterial for which kind of cell the permeability is determined, neither is it immaterial which substance is concerned in the investigations of the permeability of one and the same cell.

We shall now briefly consider the permeability of cells other than red corpuscles.

IV. PERMEABILITY OF CELLS OTHER THAN RED CORPUSCLES.

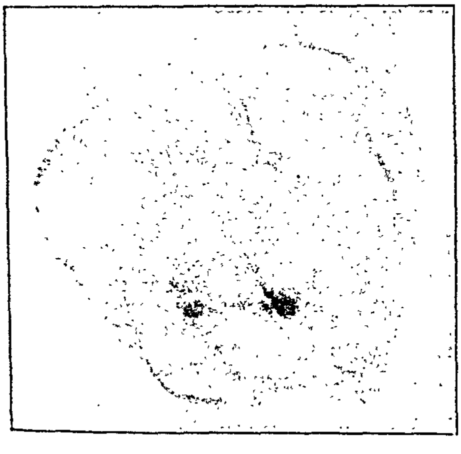
A glance at the history of the study of permeability *reveals the fact that blood corpuscles were mostly* employed. This is, firstly, because it is possible to obtain the blood corpuscles in an isolated and undamaged condition in contradistinction to most other cells. Secondly, the influence of reagents on volume and shape and on their chemical and physicochemical composition can be investigated. Thirdly, one is able, by the addition of definite substances—the amount of these substances being within physiological limits to the natural medium—to make accurate quantitative observations on the inter*change of constituents between the corpuscles and* the serum. Bacteriology has contributed much to this interest in blood corpuscles. Who does not in this connexion think of what happens after the together, sometimes, with attempts at repair; in the second, merely an evenly progressive ossifying process in an incomplete stage. Moreover—and this was my main object—mistakes can seldom arise in palpating these bones. The normal parietal at the period in question is rigid, and the only spot where localised yielding due to immaturity is liable to occur is a small symmetrical area about the parietal foramina. These foramina, or the "sagittal foramen" replacing them, lie about 1 to 1½ inches from the posterior fontanelle. The sense of weakness at this point is due to irregular spacing of the spiculæ near the margin. Except for this, which is easily excluded, the parietal at about term presents no feature due to absolute immaturity which could simulate craniotabes. Yielding of large portions of the periphery like that normal at the seventh month, and due to relative immaturity, is rare enough to be a curiosity, and in any case could not well be mistaken for anything else. In examining many of these bones, a degree of weakness sufficient to cause doubt is occasionally met with along the anterior half of the inner margin. This I at first thought to mean immaturity also, but the X ray reveals an early stage of diffuse atrophy. Such cases, in fact, occupy an intermediate position towards clinically obvious craniotabes, but need not be taken stock of in compiling morbid series.

There is thus no practical source of fallacy in diagnosing craniotabes in the newborn by clinical means.

Craniotabes in the Fœtus.

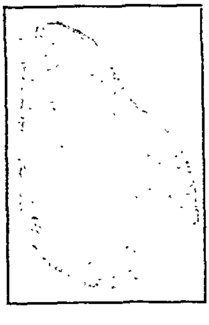
I shall throughout use the term craniotabes to denote a craniatrophy which has reached a clinically recognisable degree, and which is discovered by gentle palpation of the bone in situ. The term "infantile craniotabes" will be used to denote a craniotabes which first appears at some time after birth.

FIG. 1.



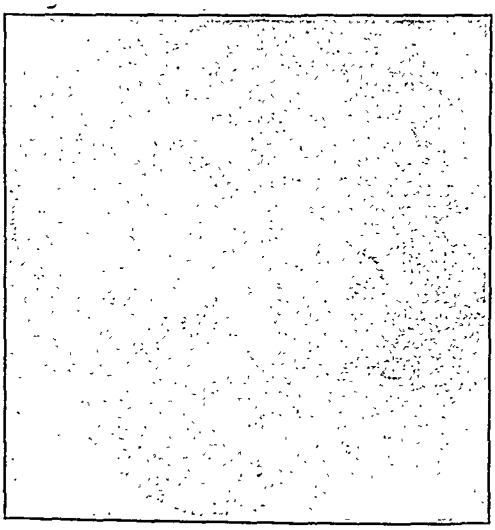
Parietal bone of subject at term with craniotabes. Note predominance of atrophy in anterior two-thirds of internal segment.

FIG. 2.



Repair proceeding in a large circular area at birth.

FIG. 3.



A normal parietal at term (vertex presentation).

The prevailing opinion, as reflected in text-books, &c., is that craniotabes is a condition developing in infancy, and it is so described. Some have remarked on the occurrence of bony defects at birth, and ascribed them to bone-immaturity. The existence also of a condition at birth deemed to be craniotabes has been recognised by some authors, but, so far as I am aware, as a rarity. Having found this latter condition congenitally with some frequency, and excluded immaturity, my wish was to ascertain whether its analogy with the infantile form was anything more than a superficial resemblance. Evidence was then gradually obtained which collectively affords a sufficient proof of the identity of the fœtal with the infantile form, and this will now be considered seriatim.

Physical Characters.

The atrophy occurs as depressions found on the inner aspect of the bone. The atrophic areas show both lacunar and diffuse formations, both being frequently present in the same bone. The lacunar areas occur as membranous spots isolated in the bone, or it may be abutting on its margins here and there. Their edges show a thinning down of the bone to the membranous or semi-membranous centre, which centre varies in my specimens from about 0·5 to 2·5 cm. in greatest width. The diffused areas may be membranous in part or wholly, or merely so far atrophied as to yield with ease. Where the bone is reduced to a thin shell, but not entirely lost, and is palpated in situ through its integuments, it is apt to feel "leathery," though still resilient; areas of total atrophy feel flaccid or "parchmenty," according to their state of tension. Any part of the parietal may be involved, but in all cases I have recorded the site of election has been the inner half, and especially its anterior two-thirds. In 76 instances (66 in vivo) the parietal was affected in all, the right alone in 27, the left alone in 13, both bones in 36. In 2 the upper portion of the frontal was also involved. The squamo-temporal and squamo-occipital were not found implicated in any.

Palpation is sufficient to settle the fact of atrophy, and to determine its main features; but in detail it is inaccurate, and this must apply also to palpation of infantile craniotabes. Parts bridged by bone are apt to yield like one, and adjacent bone, especially on the peripheral side, through loss of its normal support, sometimes seems to belong to the atrophied area. For this reason my previous illustrations, based on results of palpation, represent very imperfectly the true state of things. The radiograph now shown is sufficiently illustrative, though the definition might perhaps be improved. (The low density of these bones entails the use of a very "soft" tube.) For comparison, a normal parietal at term is included, and one showing infantile craniotabes taken as figured from Carpenter's book on syphilis in children, and given by the author to illustrate that form.

Macroscopic Details.

In parietals at birth showing normal ossification the vascularity of the bone may appear uniformly distributed, or show a degree of irregularity in this respect. In those showing craniotabes, however, there is sometimes, not always, definite hyperæmia the usual Ringer's fluid, but must be NaCl 0·5 per cent., $CaCl_2$ 0·02–0·01 per cent., KCl 0·01 per cent., $NaHCO_3$ 0·285 per cent.

As to the amount of calcium chloride, it may be emphasised that the percentage of this salt may be much greater than 0·02 per cent., provided the concentration of the Ca-ions be the right one. And this concentration is fixed *by the following formula (Rona and Takahashi*[29]*)*:

$$\sqrt{[Ca^{\cdot\cdot}]}=K\cdot\frac{[H^{\cdot}]}{[HCO_3']},\ \text{where } K=350.$$

The [H·] can be kept constant in the artificial perfusing liquid by the addition of a small quantity of CO_2 and a little neutral red. The colour to be obtained in this way must be the same as in a definite mixture of primary and secondary phosphates, as was pointed out by Sörensen.[30] The concentration of [HCO_3'] depends on the amount of $NaHCO_3$, and this amount can be determined by titration of the normal serum. It is obvious that in this way an increase of the *concentration of the calcium salt does not* affect the concentration of the free [Ca··], and, as already stated, the latter is of predominant importance.

The significance of the concentration of free Ca-ions for the permeability of cells other than the epithelium cells of the glomeruli is also evident from experiments conducted in our laboratory on the red corpuscles of man and other warm-blooded animals (Brinkman and Van Dam[31]). When red corpuscles are washed in 0·9 per cent. solution of NaCl they lose some of their colouring matter after again adding a 0·9 per cent. solution of NaCl. But this can be prevented if a definite amount of calcium-ions are present in the solution of NaCl. *The amount of $CaCl_2$ needed for this* purpose may be between 0·015 and 0·020 per cent. On increasing or diminishing the calcium hæmolysis occurs. It is not necessary in this case to use a buffer, for no acids *are formed here as in the perfusion of the kidneys.*

Experiments similar to those on the kidney were performed on the automatic movements of the rectum (Brinkman and Van Creveld[32]) and stomach,[33] and even on the secretion of the gastric mucous membrane when the vagus is stimulated (Brinkman and Van Dam[33]). The concentration of the Ca-ions must always be confined within very narrow limits, and this is effected by using the modified *Ringer's solution as well as in the normal serum.*

The fact that in normal serum the concentration of the Ca-ions is kept fairly constant may be the reason why the therapeutic application of Ca-salts is so often of no value. When acidosis exists, however, the concentration of Ca-ions is altered.

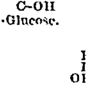
SOME REMARKS.

(*a*) *Tolerance.*—There are four other points in connexion with the permeability of the glomerular epithelium to glucose. In the first place, when the amount of glucose added to a suitable Ringer's solution is greater than that which is normally present in the blood plasma of the frog all the glucose is not held back. The amount of glucose let through increases with the amount added. It is even possible to add so much glucose that it all passes through the glomerular membrane. Is this phenomenon to be ascribed to damage done to the glomerular membrane by the increased amount of glucose? In any case the glomerular membrane becomes more and more permeable; *in other words, the tolerance of the* glomerular membrane decreases and even becomes nil. I shall not discuss this question here, only I wish to remark that the same phenomenon is observed with red corpuscles, which are also made more permeable by and to glucose.

(*b*) *Hyperglycoplasmia.*—The second point is connected in a natural way with the first. We all know that one is accustomed to speak about hyperglycæmia when the total amount of blood-sugar is greater than normal; but when investigating the relation between hyperglycæmia and glycosuria the important point is not the total amount of sugar in the blood as a whole but *the amount of sugar present in the plasma*; one must know the degree of hyperglycoplasmia. Of late years a number of investigators have studied the partition of sugar between corpuscles and plasma; most of them agree that there may be a considerable amount of sugar in the corpuscles, but only in the case of man and the dog. The experiments of van Creveld and Brinkman recently conducted in my laboratory have established in a direct manner that in circulating blood glucose is exclusively present in the plasma, and that the transit of sugar from plasma to corpuscles takes place when the blood is defibrinated;[35] the migration occurs as soon as coagulation commences, and for this reason is to be observed *even in hirudinised blood.*[36] *If, however, the blood is collected in a tube coated with paraffin and at once* centrifuged it is found that all the sugar is present in the plasma. This is of great importance for the quantitative determination of hyperglycoplasmia, which is the only matter of real importance in the clinical determination of blood-sugar. From a theoretical *point of view it is interesting to add that the* change which takes place even in the beginning of coagulation of the plasma surrounding the superficial layer of red corpuscles is sufficient to alter the permeability of the red corpuscles to sugar.

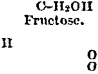
(*c*) *Phloridzin.*—A third direction in which our work on the permeability of the glomerular membrane to glucose was extended was in connexion with the influence of traces of phloridzin on the passage of glucose into the urine. Brinkman[37] found that when only 0·0004 per cent. of phloridzin is added to the perfusion liquid no trace of sugar is held back by the glomerular membrane; the renal portal vein was ligatured, so that the renal tubules could not have exerted any influence. Thus we may conclude that the glomerular membrane has been rendered wholly permeable to glucose through the phloridzin added. This permeability is perfectly reversible, so that if a Ringer's solution free from phloridzin and sugar is passed through, and then a Ringer's solution containing the physiological quantity of sugar, all the sugar is once more retained. We have therefore before us an additional example of the alteration of the permeability of the glomerular membrane to glucose, and in this case it is caused not by an excess of glucose itself, but by the foreign substance phloridzin.

(*d*) *The Reason why the Glomerular Epithelium is Normally Impermeable to Glucose; Size of the Molecule of Glucose; its Configuration; Isomeric and Stereo-isomeric Sugars.*—The fourth remark has reference to the question why the physiological amount of glucose is normally held back by the glomerular membrane. It is, indeed, remarkable that glucose is retained by the glomerular membrane, whereas other crystalline bodies, like NaCl, sulphates, and phosphates, pass through. We might imagine that the molecule of the monosaccharide glucose ($C_6H_{12}O_6$) *is so large that its passage through the glomerular membrane is hindered. We thought that if this* notion were correct disaccharides, like sucrose (saccharose), maltose, and lactose, which have a still larger molecule ($C_{12}H_{22}O_{11}$), would certainly be retained as well. Experiments proved, however, that *the glomerular epithelium is highly permeable* to these three disaccharides. It is even perfectly permeable to raffinose, which has a still larger molecule ($C_{18}H_{26}O_{14}$). Thus the size of the molecule alone cannot be the determining factor.



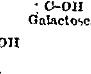
$$\begin{array}{c}\text{C–H}_2\text{OH}\\ \text{H–C–OH}\\ \text{H–C–OH}\\ \text{OH–C–H}\\ \text{H–C–OH}\\ \text{C–OH}\end{array}$$

d-Glucose.



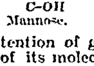
$$\begin{array}{c}\text{C–H}_2\text{OH}\\ \text{H–C–OH}\\ \text{H–C–OH}\\ \text{OH–C–H}\\ \text{C=O}\\ \text{C–H}_2\text{OH}\end{array}$$

Fructose.



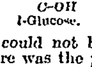
$$\begin{array}{c}\text{C–H}_2\text{OH}\\ \text{H–C–OH}\\ \text{OH–C–H}\\ \text{OH–C–H}\\ \text{H–C–OH}\\ \text{C–OH}\end{array}$$

Galactose.



$$\begin{array}{c}\text{C–H}_2\text{OH}\\ \text{H–C–OH}\\ \text{H–C–OH}\\ \text{OH–C–H}\\ \text{OH–C–H}\\ \text{C–OH}\end{array}$$

Mannose.



$$\begin{array}{c}\text{C–H}_2\text{OH}\\ \text{OH–C–H}\\ \text{OH–C–H}\\ \text{H–C–OH}\\ \text{OH–C–H}\\ \text{C–OH}\end{array}$$

l-Glucose.

If the retention of glucose *could not be ascribed* to the size of its molecule there was the probability that a characteristic structure or configuration of the glucose molecule had something to do with it. For this reason some sugars which were either isomeric or stereo-isomeric with glucose were experimented with. For the sake of convenience I give above the formulæ of a few of these sugars.

recognisable craniatrophies at birth. This is well explained for many by supposing the skull at birth already prepared for further craniotabes by a degree of atrophy in the posterior segment as yet unrecognisable to palpation, and *not to be detected* by any but radiographic means. It is, moreover, in this *quadrant, part of the segment most prone to atrophy in fœtal life, that I find* infantile craniotabes to more commonly begin. It may also be observed to start from the *thinned margins of small atrophic* areas found in the posterior segment at birth. Such con*siderations may explain why most infants escape* post-natal craniotabes, though subject to like con*ditions. But it may be also plausibly argued* that the organic causes of decalcification present in the fœtal state are carried on into infancy.

Enough has now been said to indicate that the *inception of craniotabes* as a pathological event must be relegated to fœtal life, if not always, then very *often.* In connexion with the whole argument the absolute frequency of pre- and post-natal forms needs to be worked out. My own *figures* (industrial population of Liverpool) give so far for all grades of the fœtal form 21·6 per cent. (60 out of 277 unselected vertex births). A series of still-births furnished ten examples in about 63 (in a few of these the presentation was uncertain). For the infantile form a recent probable estimate by Wieland[4] gives about 20 per cent. of *all* infants, presumably studied in a city district. These figures, so far as they go, tend rather *to support the thesis just advanced.*

Infantile Craniotabes.

My material here is 100 cases, but any deficiency in point of numbers has been, as I venture to think, more than compensated for by the method of continuous and intensive study given to individuals. *Results as to localisation* agree closely with those of Carpenter, who found the occipital seldom affected *in comparison with the parietal. In all my cases* where the occipital was affected, there was at some *time more pronounced or extensive atrophy in the* parietal, and there was evidence or proof that the former was *involved secondarily in point* of time. The occipital, however, may be the last to heal. The statement of Stoeltzner[5] that craniotabes is only found after the first three months is *contradicted by* my results, numbers developing during the second month. The earliest began in the fourth week, the latest at the end of the fourth month. Most, however, reach a maximum by this latter age, and thereafter begin to regenerate. The mechanical conditions furnish the key to the period of incidence. Relief of pressure is brought about earlier in some than others, *but in most is sufficiently accomplished by* or before the end of the fifth month. Accordingly we find craniotabes disappearing after this time, *given relief* of pressure, whatever the child's state of health may be. Difficulty has been felt by some[6] in assigning the same pathology to diffused and lacunar formations. This I do *not* share, since the same case may represent the lacunar form when it begins, the diffuse form at its full development, and the lacunar form again as it heals. In areas widely atrophied, remnants of partially calcified tissue are often left, and regeneration occurs from these as well as by irregular invasions of bone from the centre of ossification. The result is that a broadening trabecular arrangement of new bone is apt to be formed, enclosing ever-dwindling atrophied spaces. If the case *is first seen in this last* phase, it may appear sui generis, especially since manifest rickets may be present at these ages. The variations in contour of the back of the skull may be held responsible for some of the varieties in form and position met with.

Organic Causation.

The mechanical causation of this curious condition is clearly only a part of a causal nexus. Though the great majority of individuals are subject to closely similar mechanical conditions, only a minority—say one-fifth—develops craniatrophy to the clinically recognisable degree. In this minority, therefore, decalcification must be promoted by some morbid agency. Here I shall deal with syphilis and rickets (or rather, the as yet unknown causes of rickets) † as possible morbid agencies, in the light of such data as the present inquiry can contribute. I find it possible for a child to have fœtal followed by infantile cranio*tabes, and to pass through infancy and earlier child*hood without showing any sign of either disease; but this observation has little real weight. Rickets may be arrested before it is clinically demonstrable, and syphilis may remain clinically latent. Most craniotabetics show either one or both; and by different schools of opinion the causality of both, *separately or combined,* has been asserted, though as a rule with little serious attempt at proof. The problem is by no means an academic one, seeing the therapeutic needs of child and mother on either assumption, and the importance to the theory of rickets of a decision on the matter.

Regarding syphilis first, its relation is beyond dispute, for it is consistently present in series, including my own, to as much as 50 per cent. or more. These findings, moreover, are based on clinical *evidence, and a positive residuum over and above* this must be allowed. From historical analogies, the argument, therefore, seems *a fairly strong one* for the necessary antecedence of syphilis; but the connexion needs examining further. Carpenter, who devoted long attention to this subject, estimated that about 50 per cent. of congenital syphilitics show craniotabes. If the above estimate of about 20 per cent. of all infants is also near the mark, we should then be required to assume that some 40 per cent. of infants, in our city populations, are born with syphilis —an estimate very widely in excess of any yet made on other grounds, clinical or pathological.

The same observer prepared charts showing the coincidence of craniotabes with the manifest syphilis *of the earlier months.*[7] *Granting the coincidence en masse,* we have yet a very good mechanical reason for the predominance of craniotabes at these ages, quite apart from the activity of an accompanying syphilis; moreover, the coincidence largely disappears on going into detail. The maximum of each is generally reached at different times, and if individuals are studied in continuity, their craniotabes is found to have an independent career, determined by the pressure conditions. Moreover, craniotabes shows indifference to an otherwise successful course of mercury. This rule has been uniform in my experience when cases are chosen at the right time, say those starting in the second month, which nearly always will spread in natural course. It is useless to select cases at the period of natural healing, since this goes on at differing rates. It is also noteworthy that extensive cases *sometimes run their whole* course without any sign of syphilis. In 10 stillborn instances examined, *S. pallida* was not found in liver, spleen, and lung, and the Wassermann reaction, taken in 9, was negative.‡

While such considerations, together with other points not now enumerated, all go to discredit the causal agency of syphilis, its more remote causality could not well be excluded so long as we are largely ignorant of its power of injuring the fœto-infantile mechanism of calcification, and while it seems possible that some cases of low virulence and latency escape our present methods. I find it, however, more rational to regard its action in that kind as nonspecific, and its association with craniotabes as having the same meaning *as its association with* rickets, which in the human subject is deceptively close, the action in both conditions being to promote resorption of bone. In other words, were it not for the presence of syphilis, many of these craniatrophies would not have time to reach a degree where they can be clinically recognised.

---

† All that is up to now determined is *the agent, or one of the* agents, preventing rickets. The causes producing it come into play after the preventing *agents are* removed. These causes are unknown.

‡ I have Prof. Beattie's permission to mention these results, which were obtained in his laboratory.

experiments of Neuschlosz,[40] who found that an emulsion of lecithin in water possesses a surface tension dependent on the amount of Ca present. Too much or too little Ca had the same effect. In the therapeutic application of lime salts one also often notices opposite effects according to the amount used.

To return for a moment to what Prof. Bayliss has called the "Clowes's effect," it would seem that the view of the American author is strongly supported by our experiments on the stereo-isomeric sugars. We have seen that pores are left between the oil-drops, and it is obvious that these pores, because they are subjected to the surface tension at the boundary, assume varying shapes. Now pores of a definite shape could allow sugars of a definite configuration—e.g., lævulose—to pass through, while holding back sugars—e.g., glucose—of another configuration. One might be inclined to explain this phenomenon by the aid of differences in viscosity or surface tension. But we have found with Miss S. C. Hamburger that these physical constants are the same for lævulose and for glucose. How can one explain this separation of glucose from lævulose, therefore, other than by supposing that the shape of the ultra-microscopic pores in the sieve plays a decisive part? Our experiments thus lend support to Clowes's theory, and vice versa the mechanism of specific permeability has become clearer.

Finally, it may be said that the conditions shown in our sketch by the portion below the line do not, as a rule, occur in physiological circumstances. In fact we know that, as a rule, all the cells of the body are permeable to water. But there are exceptions. When blood is diluted with a great deal of water most of the red corpuscles in absorbing water loose their colouring matter and the mixture has become transparent. But after centrifugalising I often saw a deposit which examined by the microscope proved to consist of red corpuscles. These cells must have been impermeable to water. Red corpuscles treated with cobra venom are also impermeable to water, and the same is true of the eggs of sea-urchins.[41] When put in distilled water the latter does not enter the eggs, as Ralph Lillie has pointed out, but on adding some Ca-ions their impermeability to water is lost.

CRANIOTABES OF THE FŒTUS AND INFANT.

BY EDMUND HUGHES, M.R.C.S., L.R.C.P. LOND

IN a previous paper[1] I recorded some results of a clinical inquiry into this subject. The account then given was composed under the combined disadvantages of military service and paper shortage; and this was unfortunate, because the contentious nature of certain of the findings called for their rather full presentment. I shall therefore make no apology for re-stating these findings in somewhat more adequate form.

Broadly, the position then reached was that the recognised "craniotabes" arising during the first few months of infancy is in many, and probably in most, cases only a fresh manifestation of a state of craniatrophy already existing in later fœtal life. This fœtal craniatrophy, having no physical differences from the later form, and occurring predominantly in the same individuals, was therefore held to deserve the same title. Verification of this finding would entail a re-scrutiny of the common belief that craniotabes is a sign of rickets. A simpler solution of the difficulty would be to infer the causality of syphilis. But the only definite contribution to the problem of causality I was able to make consisted of some fresh evidence tending to rule out syphilis as an acting or proximate cause. The evidence given was, I think, sufficient for that purpose; and it must be remembered that observation alone, though powerless to decide what is causal, can often determine what is not.

I will now go over the previous findings, incorporating such fresh material as has since been obtained. The total case-material is 154.

Immaturity of the Skull.

In connexion with yielding areas in the skull at birth, the problem was early raised in course of this inquiry as to what characters of this kind in the newborn skull can be legitimately ascribed to immaturity. To determine this point, a parallel study was made on some hundreds of living neo-natal crania at various stages of development, and of stillborn and non-viable crania, in situ and detached.* Seeing that in all my cases of fœtal craniotabes the parietal bones were attacked, and that all were born at or near term, interest here centres on the condition of the parietal at and near the end of the fœtal period. The result of study makes it clear that the condition I call fœtal craniotabes and the condition of the parietal due to immaturity are entirely distinct. In the first there is discontinuity of the bone-forming spicules—a true atrophy in some part of their course—

---

* For the great majority (about 130) of these latter my thanks are due to Prof. J. M. Beattie, who kindly placed at my disposal the stillborn material brought to the Liverpool City Laboratory. This material has also furnished several morbid specimens.

would have escaped through the bladder wall without reaching the general circulation.

Various Preparations of Antimony.

As a rule the sodium salt of antimony can be given in larger doses than the potassium salt; but I have had patients under treatment with the sodium salt who manifested rather severe toxic effects, such as one sees only with the larger doses of the potassium salt, and I do not find it as effective as tartar emetic. I have treated a number of cases with a preparation of antimony, acetyl paraphenylendiamine antimonyl tartrate, which Messrs. Allen and Hanburys had prepared, and hoped would prove less toxic than tartar emetic. I did not find it appreciably less toxic than an equivalent dose of tartar emetic, though I was able to effect permanent cures by its aid. In several cases I employed Oppenheimer, Son and Co.'s colloidal preparation of antimony, oscol stibium, and a patient of 14 could tolerate up to 7 c.cm. given intravenously without the slightest toxic effect. However, to produce a permanent cure with this preparation alone I found it necessary to press the doses until such toxic effects as diarrhœa and a rise in temperature show themselves. In using this colloidal preparation of antimony in the intramuscular treatment of several leper patients, I also found that the best results were obtained when the patient was well under the influence of the drug, and from what I saw of the lepers on Robben Island, who at my request were being treated with antimony in April of this year, I have no doubt that the non-toxic doses that were being given were responsible for the smallness of the results obtained. By treating a number of bilharzia cases with Crookes's collosol antimonium I have shown that this preparation of antimony also produces a like process of degeneration in the ova that escape in the urine. Much caution must, however, be made in regard to the supposed value of colloidal preparations unless we can be sure that the supplies we receive are stable, as I believe both these products now are.

Treatment with Manganese and Arsenic.

I have had good results in the treatment of cloudy and offensive urines with intramuscular injections of colloidal manganese, but neither manganese nor arsenic appears to have any effect on the bilharzia worms in these cases. One patient of 19 received 11¼ gr. cacodylate of soda intramuscularly or subcutaneously in August, 1920, and 76 c.cm. of diemenal in October without any appreciable change in the ova, though the urine itself was much clearer. However, the condition soon cleared up with a few doses of emetine, the largest dose given in this case being 2½ gr. intramuscularly.

Successful Treatment Indicated by Black Ova.

It is not at all uncommon to see black ova in the blood-stained urine of patients who have received no treatment, and during an attack of colic ova are often seen in all stages of degeneration. It is the gradual increase in the signs of degeneration and the gradual disappearance of the ova until none but black ones are seen that warrants the assertion that a remedy is proving successful. It has been suggested that the adult worms are destroyed by only a few doses of antimony and that the subsequent doses are required only for the ova; but I have had under me patients who discontinued treatment after two or three weeks with a gradual return of their symptoms, whilst the number of degenerated ova have gradually been replaced by perfectly normal ones, suggesting that some of the adult bilharzia worms that escaped destruction had entirely recovered from the effects of the drug.

Infusion of Berkheya.

I heard that a kaffir root was very effective when given as an infusion. It proved to be berkheya (*Stobœa speciosa*), but a fresh infusion in rapidly increasing doses had no effect on two cases. There is the possibility of a local unknown specific plant, but in view of the presence of *Schistosoma bovis* infestation in South Africa it is also possible that the relative [illegible]ity of some persons is due to the ingestion of [illegible]fested meat.

Emetine Hydrochloride.

As emetine hydrochloride has been recommended in the treatment of bilharzia disease, I determined to give it a thorough trial in Natal. I was fortunate in having the clinical condition confirmed in all the cases by the results of microscopic study, and in several of them by the complement-fixation test as well. One of the drawbacks to this method of treatment is the cardiac depression which may develop in some patients during the second or third week if emetine is used without any other drug to counteract this effect. The cardiac depression which is indicated by a small rapid pulse readily responds to treatment with small doses of digitalis, but can generally be avoided if the dose of emetine is skilfully regulated and the following tonic prescribed:—

Ferri et amon. cit.	gr. v.
Liq. ars.	♏︎. iii.

Inf. gent., ad half ounce in water t.d.s.a.c.

Even with the larger doses of emetine which are required and can be given on alternate days, I find that local reaction causes only very slight inconvenience to the patient if the emetine is dissolved in 20 mm. of a 1 per cent. solution of carbolic acid, which can be boiled along with the hypodermic syringe and needle. It is best not to use the same site for an intramuscular injection more than once. Should the muscle become sore, a hot sea-water bath on one of the days when no injection is given is very gratifying. Intravenous injections of emetine may cause immediate cardiac depression and are better avoided. I was surprised to find intravenous injections no more effective than intramuscular injections.

I have obtained the best results by giving an intramuscular injection daily for three days and then three times a week for three weeks. I generally commence with an initial dose of ½ gr. for an adult and ⅓ gr. for a child. A dose of 1 gr. is a sufficiently large one to work up to in a child of 12. Vomiting may occur if the injection is given shortly after a meal. The maximum regular dose for an adult may be regarded as 2 gr., but larger doses appear to cause toxic effects and to cure more rapidly. The accumulative action of emetine is almost as marked as the acquired tolerance for antimony, and the dose should be lessened or given less frequently towards the close of treatment. Our aim should be to keep the patient well under the influence of ipecacuanha without producing undesirable toxic effects. A slight return of albuminuria after the urine has cleared sometimes indicates toxæmia, and—as with the antimony treatment—suggests that the injections must be given less frequently or the dose lessened. It is generally necessary to continue treatment for about 25 days.

A. H. Harkness has reported[2] that 14 gr. in two weeks and 20 gr. in three weeks proved ineffectual in an adult; but Diamantis, of Cairo,[3] reported that 0·85 to 1·05 g. (from about 13½ to 15½ gr.) was generally sufficient to cure a case if 10 to 12 injections are given at intervals of from three to five days.

Conclusion.

My experience in Natal shows that the emetine treatment carried out along the lines I have described is undoubtedly a better way of treating children and young persons than that which involves intravenous injections of antimony. The progress of a case can be determined with certainty only by the microscopic examination of the centrafugalised deposit of urine passed, and it is the last portion which contains most of the ova. By examining the urine in this way I have observed the same degenerative changes taking place in the ova of *Schistosoma hæmatobium*, *S. mansoni*, and *S. bovis* whilst patients were being treated with emetine as those which are commonly associated with the antimony treatment.

Towards the expenses involved in this research a grant was received from the British Medical Association.

Durban.

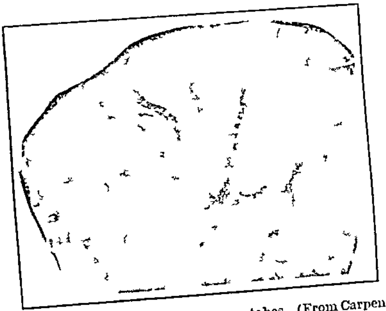
with an irregular distribution This is best seen in more advanced examples, and after hardening, when their dark colour is in sharp contrast with the appearance of normal specimens The hyperæmia is seen to be more pronounced in a broad zone round the atrophied parts The pericranium is not noticeably thickened This structure is often ill developed at birth, and may not strip very easily off a normal bone It usually strips off an atrophied site, though the presence of old blood may cause partial adhesion and pigmentation The same description applies to the dura, which, moreover is thinned over membranous sites One naturally thinks of intra partum damage in these cases but in my confinement series only one stillbirth occurred probably from unrelated causes, the others seemed none the worse, then or afterwards Though numbers have been re observed at later ages no evidence of cortical injury has been met with The following shows, however, the intra partum possibilities in a rather extreme case—a still born female infant in my laboratory series —

FIG 4



Part of parietal showing infantile craniotabes (From Carpenter)

There was much inner segment atrophy of both parietals, chiefly diffuse and partial The left showed a fracture 1¾ inches in length, parallel with the sagittal edge and involving the thinned bone near its junction with normal bone The pericranium here was torn through, and a layer of recent blood extended beneath it as far as the eminence The underlying dura otherwise uninjured, was separated from the bone by blood and serum (commencing internal cephal hæmatoma) Further forward both dura and pericranium were partially adherent to the atrophic bone up to the fontanelle, the adhesion being due to a thin deposit of old (ante partum) blood The subjacent cortex was apparently undamaged

One would expect sub pericranial hæmatoma after the birth of severely tabetic skulls especially where the margins were diffusely atrophied Of 11 examined post mortem, three showed atrophies of this type, and in all three there was commencing hæmatoma Till recently, the significance of this point had unfortunately escaped me so that the absence of record of it among those that survived may mean a fact or an omission As this accident, however, probably occurs in under 1 per cent of all births, it is unlikely to complicate these cases with any frequency, at any rate to a clinically obvious degree But when present, especially on both bones, the possibility of underlying craniotabes may be borne in mind The histology of these bones will be given in a later note

Mechanical Causation

This is the only certain element in the causal nexus of craniotabes in general Yet that it has sometimes been disregarded is shown in the statement of Carpenter[*] that craniotabes (infantile) cannot be a sign of rickets because it is getting better while rickets is developing, and by an argument quoted from Wieland[3] that the imperfectly ossified areas occurring in the newborn do not mean craniotabes because they occupy a different part of the bone. This latter is also an error of fact, as they may be found in the same part, but the observed differences of position at the two periods is exactly what would be expected if the two conditions were identical At both periods they occupy the most dependent regions of the skull, the regions of maximum strain Again, it is a mark of a true cause (in action) that when removed its effect (if impermanent) always begins to cease from that time forward Events were followed in some fifty or more of my cases, and in all progressive repair was observed to take place where (as is usually the case) the fœtal area was situated outside the new regions of pressure after birth

The physical characters tell the same tale In the normal majority of skulls at term, the indentations accommodating the cortex are as yet ill marked and scanty Craniotabes (in general) implies a morbid exaggeration of these in dependent parts For the fœtus, and in head positions, one must infer a double force of compression tension for both inner and outer strata The design of the parietal bone bears out this inference, at any rate for the outer stratum There is, of course, no diploeic space at this age The inner layer is thin and compact the outer layer, in contact with the inner, and about two to three times its thickness I find to show partial interlacement of the radiate fibres together with a general tendency to slant from the inner towards the outer surface from centre towards periphery This latter arrangement, so far as it exists, would tend to equalise strains from external pressure, and to transfer them towards the stronger interior bone Owing to the general structure, external compression strain would tend to be transferred to the apex of a wedge of strain whose base is on or faces the margin and this so far as there is need to assume it, would help to explain the frequent occurrence of atrophic holes in the interior Internal compression by the semi diffluent brain mass of the fœtus should be moderately uniform but with a gravitational stress concentrated on the inner segment The greater tendency to diffused and other atrophy in this segment is, no doubt thus accounted for One can only postulate the main features of so irregular a mechanical system as the whose complexity is increased by the various fœtal movements and by such developmental variations as may occur in the bones themselves There is further to be included the inconstant lie of the head in relation with the uterine wall, the obliquity of the uterine axis &c The greater implication of the right parietal is of interest in connexion with the lower lie of that bone so far as gravitation is concerned, in first positions, while the general anterior position of these atrophies together with other points should help in determining the normal stresses on the fœtal head prior to labour I have only found craniotabes in births by the vertex Its occurrence in other than head presentations would indicate that the fœtus had recently changed its position

Clinical Course

Rigidity of the fœtal area removed from stress is generally accomplished, clinically speaking by the end of five weeks, but repair may be much more gradual and prolonged to three months The finding of areas far forward during infancy, if this is not far advanced would mean their origin in the fœtus During the first four months of infancy fresh areas in the posterior segment are very liable to develop and the case then becomes one of infantile craniotabes which subsequently runs its usual course This sequence occurred in 33 out of the 38 which I was able to follow up Of 117 born without recognisable craniotabe , and followed to some part of the fourth month 10 afterwards showed it Allowing for modification by larger figures the discrepancy found (about 86 as against 8 per cent) is still great enough to justify my inference that the bulk of infantile cases are recruited from those showing

Source of Infection.

From the slow spread of the disease from one boy to another, and the fact that there was no generalised outbreak involving a number of the boys at one time, it was considered that the food, drinking supplies, &c., could be excluded, and that the infection was probably coming from a "carrier." The persons most likely to occupy this rôle were two assistant masters and two boys who had spent a great part of their lives in Baghdad.

The history of these cases was as follows: Mr. X., assistant master, an ex-soldier who had been in France for a short time, and Mr. Y., assistant master, in France for two years; A. S., a boy, aged 14, who came to England from Baghdad on July 23rd, 1920, and entered the school in September, 1920. There was no history of enteritis in any of these three. The other boy, A. H. S., aged 14, also came from Baghdad on July 23rd, 1920, and entered the school in September, 1920. He had had an attack of slight diarrhœa two years previously while at Baghdad.

The examination of fæces of the two boys from Baghdad gave the bacteriological findings as shown in Table IV.:—

TABLE IV.

Cases.	MacConkey plates.		Glucose.*	Mannite.	Litmus milk.		Indol.	Motility.	Macroscopic agglutinations.		
	L.F.	N.L.F.			1st day	3rd day			Flexner	Shiga	Y
A. H. S.	+ +	1 col.	A	A	Acid	Alk.	—	—	1/1600	0	1/800
A. S. ...	+	Nil	—	—	—	—	—	—	—	—	—

* Lactose, dulcite, saccharose, maltose = Negative results in each case.

The blood serum from suspected carriers and one control gave the results when agglutinated against *B. dysenteriæ* Flexner-Y stock culture, and the Southport organism, as shown in Table V.:—

TABLE V.

Cases.	Flexner-Y stock culture.	Southport organism.
A. H. S. ..	1 in 100	1 in 20
A. S.	1 „ 300	1 „ 100
Mr. X.	Negative.	Negative.
Mr. Y.	„	„
Control	„	„

Conclusions.

The details given above show that an infection with *B. dysenteriæ* (Flexner) had occurred in the school and that it was highly probable that the source of infection was a carrier, the evidence being strongly in favour of the boy A. H. S. With regard to this boy, the first two specimens of his fæces to be examined were negative, and the third specimen yielded but one colony of *B. dysenteriæ*. The infection commencing in a mild form assumed increasing virulence, the last case, G., being acutely ill. The seven mild cases, and two boys under suspicion of being carriers, still carried agglutinins to the isolated strains from the acute clinical cases, and also to Stock *B. dysenteriæ*, Flexner and Y strains; it is therefore strongly suggested that although the organisms were not isolated in six instances the infection had been present previously. Two of these, C. M. and A. C., from whose fæces the organisms had been isolated, were among the three highest agglutination reactions obtained.

The bacteriological examinations were made by Dr. Cronin Lowe, pathologist and bacteriologist to the Southport Infirmary.

WELWYN HOSPITAL EXTENSION.—The rebuilding of the Queen Victoria Memorial Cottage Hospital at Welwyn has now been completed at a total cost of £4000. In addition to a new operating theatre and anæsthetic room, three new private wards have been added. These will be available at 4 guineas a week for private patients attended by their own doctors, or in the case of operations by surgeons not necessarily on the staff of the hospital.

A CASE OF MORAL IMBECILITY.

BY W. NORWOOD EAST, M.D. LOND., M.R.C.S.,
SENIOR MEDICAL OFFICER, H.M. PRISON, BRIXTON.

(*With the Permission of the Prison Commissioners.*)

THE subject of this sketch, a woman at one time under the prolonged observation of the writer, and then approaching middle age, presents in the ascertained incidents of her career features so distinctive of moral imbecility lasting over a period of many years, and doubtless not yet concluded, that some record may be of interest. Many of the facts now related were obtained from an excellent report which cannot here be extensively quoted. In the abbreviated account which follows places and personalities are disguised.

Of the many aliases assumed by the prisoner, the simplest known was that of "Jane," by which name she will be known in this account. Jane was possessed of an intellectual capacity considerably above the average for her station in life; had her ability been associated with normal moral development a happy and honourable career could have resulted. Her parents were humble and honest, and Jane, their eldest child, was born in wedlock during the second year of their marriage. The remaining members of the family are said to be of irreproachable character. There is no record in the family of insanity, epilepsy, nervous disease, intemperance, or criminality, and Jane herself, whom I questioned closely on this point, denied any such history; perhaps on this occasion she may have spoken the truth.

After attending various schools, from the last of which she was dismissed for pilfering, Jane was described as having a good but superficial education, as being a singer and pianist of more than ordinary merit, with attractive conversational powers.

Early Sexual Delinquencies.

It is clear that from an early age she possessed a personality which fascinated those men she elected to attract; and this fascination apparently remained with her in later years. It is still conceivable that, suitably gowned, her appearance, manner, and address could command attention, but whilst under observation none of the wiles of the courtesan was noted; her attitude and demeanour at that period suggested frigid chastity. At about her puberty her father died. At the age of 15 Jane became intimate with her mother's lodger, a man considerably her senior, who married her when she was 17, the baby being born shortly after. Quarrels due to her reckless extravagance, involving her husband in debt, soon caused this ill-assorted couple to separate. When re-united husband and wife went from one lodging to another; in five different houses in which they stayed money saved by the landladies for rent was stolen, and mysterious fires broke out. At this period of Jane's life a second child, a cripple, was born; Jane neglected home and children for a gay life, and money saved by her husband to obtain medical treatment for the cripple was spent in dress. Ultimately, as she constantly came home late—often accompanied by men—her husband revolted, and when she admitted immorality they parted and did not come together again.

Before their final rupture Jane made the acquaintance of a lady, Mrs. X, to whom she posed as an heiress having a guardian, Mr. Y. This romance, with variations, has been frequently repeated during her career. On leaving her husband she found employment with a City firm, and occupied rooms in a boarding-house, but her stay was short, for the landlord turned her out on account of the number of men she brought home. From there she went to the seaside, and for the first time in her life, early in her third decade, came into the hands of the police and was convicted for stealing from her lodgings. She was bound over on promising to go into a home, but absconded, demonstrating her lack of a sense of honour.

Regarding rickets, my observations suggest that it is clinically associated with much the same frequency as syphilis. Though the severity of craniotabes and a subsequent rickets often varies directly, this ratio is quite inconstant. The feeding in 105 cases when first found with infantile craniotabes (extreme ages 1 and 9 months) was: exclusive breast-feeding, 62; mixed feeding, 14; exclusive hand-feeding, 29. In the breast-fed the atrophies were not less extensive, but usually partial in degree. That so many were breast-fed is against expectation, but it may be argued that, ceteris paribus, if the maternal blood cannot prevent craniotabes the maternal milk will not be able to prevent it afterwards.

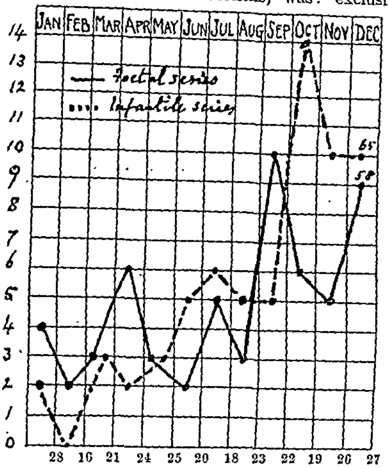


FIG. 5.—Chart showing the months of birth of 123 craniotabetics.

The point on which observation can best help theory appears to me that of seasonal incidence. This is now being worked out. The results so far are shown herewith, though their inadequacy as yet is patent. The month of birth is stated for 123 in which it is known. The infantile series includes cases only observed with that form. In the fœtal cases (58) an error involved in such estimates can be checked by knowing the number of births per month among which they occurred (see foot of chart).

It seems, therefore, that a seasonal curve may exist. Thus *51 per cent. of the fœtal series, and 60 per* cent. of the infantile, were born in the last four months of the year. Supposing the bulk of fœtal cases to show infantile recurrence, it would follow that infantile craniotabes will be chiefly met with, at any rate in its worst degrees, in the first few months of each year.

If a marked winter aggravation is confirmed by larger figures, it will serve to that extent to ally craniotabes with rachitic phenomena in general. But the chief difficulty remains. We have seen that the early disappearance of craniotabes is no obstacle to its acceptance as a true sign of rickets; but its early appearance constitutes a difficulty which has already existed for the earlier infantile examples, and is only somewhat increased by bringing in the last few weeks of pre-natal life. A partial solution may be attempted, however, by recognising the influence of stress on the individual bones in determining the order of rachitic bone changes in general. Such knowledge as we have indicates that the stresses on the fœtal long bones are generally less intense than those obtaining in the outer world. But the stress on the dependent cranium must be considerable, both by its position in the relatively rigid lower *uterine segment*, and by the interior brain-mass for some 16 hours out of each 24, the total stress being probably greater then than after birth. Add to these considerations the partial immunity of the fœtus against adverse maternal influences, and the possibility, by analogy, that any such effects might be shown in a modified form at these early periods, and the difficulty becomes, perhaps, less formidable.

With this particular problem, however, observation can do little, and one awaits the results of the experimentalist, especially on such subjects as the effects on the fœtus of ill-balanced maternal diets involving deprivation of vitamin A, and the causes of osteomalacia.

ANTIMONY AND EMETINE IN BILHARZIA DISEASE.

BY F. G. CAWSTON, M.D. CAMB.

IN 1917 Dr. J. B. Christopherson established tartar emetic as the routine treatment for bilharzia disease in Egypt, and no equally effective but less toxic preparation of antimony is at present available. Undesirable results of unskilful administration of the drug are still being experienced in various parts of South Africa, the solution causing necrosis through being injected under the skin instead of into the blood stream. Sometimes large doses are given before the usual tolerance for the drug has been acquired, and occasionally the doses given are too small to produce any appreciable effect on the parasites.

During 1920 I recorded[1] my results obtained by treating a number of cases of bilharzia disease by intravenous injections of a freshly prepared solution of tartar emetic, the injections being given on alternate days shortly after a light breakfast, the dose varying from ½ gr. to 1½ gr. The doses were gradually increased until the largest dose that the patient could comfortably tolerate was reached. The subsequent history of these and other cases show that, where the *injections are given regularly over a period of 28 days*, there is little possibility of a return of the symptoms. A dose of more than two grains is unnecessary; larger doses do not appear to effect a cure any more rapidly. It is always risky to discontinue treatment before the 28th day or to give the injections less frequently than three times a week. I have seen recurrences when 15 gr. have been administered over a period of 24 days and others where four days have been missed in the middle of treatment, but none where treatment has been continued without interruption for 28 days, even though no greater total dose has been given.

The powder was dissolved in from 4 to 12 c.cm. of boiling distilled water just before being drawn up out of a wide-mouthed test-tube into an all-glass serum syringe which had already been sterilised and had a suitable needle attached. *It has always been my* practice to boil both needle and syringe before use, and to paint the skin with rectified spirit before injecting the needle, and I see no reason to alter this procedure. Without discolouring the skin, spirit rapidly produces a clot which helps to arrest bleeding and assists in rendering the seat of injection both aseptic and anæsthetic. Incompletely cured cases of bilharzia disease are especially liable to attacks of renal colic, and when the general health does not rapidly improve after treatment it is generally because all the parasites have not been destroyed. These attacks of colic which sometimes occur during the course of treatment are probably due to an accumulation of incompletely destroyed ova in the kidney substance, which, under ordinary circumstances, becoming null and void; the proceedings were reported in the press, and so the facts became known to the superintendent, who washed his hands of her. Jane then returned to the home of the rescue-worker, who had previously befriended her; she was then pregnant. As before, soon after her arrival money mysteriously disappeared, until outside Jane's bedroom window was found a bunch of keys which opened almost every lock in the house. One night the telephone wire to the house was accidentally found to be cut; the house was searched, and behind the curtains in Jane's bedroom was found a pile of inflammable material saturated with petrol ready to be fired, together with a bottle of chloroform. It is not clear for what purpose this drug was obtained, but the chance discovery of the cut wire probably averted a crime and perhaps a tragedy.

---

[1] THE LANCET 1920, ii., 392.

On the birth of her child in a maternity home the Roman Catholic priest who ministered to Jane, apparently apprehending the possibility of injury to the infant, urged its baptism at the earliest opportunity. Jane, who was brought up in this faith, ultimately consented; the Roman Catholic sisters received the child, and the baptism took place in their chapel. On their return they discovered Jane had substituted the infant of a Protestant girl for her own. Eventually her own child was baptised. When she recovered from her confinement, the child—admittedly Mr. Z's—was put in the care of a woman, next door to whom Jane took private lodgings. One of her landlady's children was ill about this time, and Jane informed the mother she was going to consult a professor, with whom she was on terms of intimacy, about the child. On her return she reported the professor was coming next day to operate, and much fuss and elaborate preparations resulted; but as the doctor did not arrive the child's father, after waiting some time, prepared to go out. At this moment Jane raised an alarm of fire. The dining-room sofa, well away from the fire, was burning; much damage was done to the room, and the husband did not go out. A day or two later his gold watch and chain, only worn on special occasions, were missing.

Posing as a Nurse.

The next episode shows Jane in an even more sinister light. In the same city a gentleman advertised for a nurse to take care of his wife dying of cancer. Jane, calling herself a nurse, was engaged, and money was handed to her to obtain comforts for the patient. No comforts were provided and the money was not seen again. A night or two afterwards Jane was discovered bringing men to the house, and instead of being with the patient during the night was frequently absent. A few days later a maid entering the sick-room found a rubber tube connected to the gas burner lying with its open end on the invalid's pillow. The following day Jane was discovered bending over the patient with a bottle of chloroform in her hand. When asked to explain her behaviour she alleged she was carrying out the doctor's instructions in the matter of the gas and the chloroform, which statement he, of course, at once repudiated. It was also observed that the patient seemed worse after her medicine had been administered, and on the day of her death Jane had neglected to supply her with hot-water bottles as directed, saying the doctor had told her not to do so, as the patient would die that day. Jane was turned out of the house, indignantly protesting at her treatment. After the funeral it was ascertained that much of the deceased's clothing was missing; some was found in Jane's box, but the police were not informed and she was not prosecuted.

Another Marriage.

Once, when short of cash and borrowing money from her landlady, she invited her to a meal in a fashionable restaurant. The invitation was accepted, and Jane paid the bill with a sovereign; on returning home the landlady found a sovereign missing from her purse. At another time Jane made the acquaintance of two students—friends. One immediately fell in love with her and they lived together, Jane alleging she had sufficient means to support them both. Within a week she had cast this one aside, and told him she loved his friend. A fight between them ensued, Jane was wounded with a knife, and two days later married the second student, by whom in due course she had a child. On leaving him she entered a lady's employment as nurse; three days later a bed was found to be on fire. A few days later a valuable diamond ring was missing and found in Jane's bed; shortly afterwards again, another mysterious fire broke out, and further thefts of money and jewellery occurred.

Again Posing as a Nurse.

Soon after leaving here she became nurse to an aged and infirm lady, securing the appointment by recommending herself for the post by telephone. She then attempted to obtain money from the patient's acquaintances under the pretence that the invalid was in financial straits, which was untrue. In this she failed, but it was found that large sums of money and jewellery belonging to the patient disappeared, and a bed in the servants' bedroom mysteriously caught fire. Two days before the patient's death Jane was summarily dismissed, the reason not being made public. She was watched, arrested, and charged with being in possession of clothing and jewellery belonging to her late patient; these Jane said had been given her by the deceased, and as no one was in a position to contradict this she was not proceeded against.

By this time sufficient evidence had accumulated to show she had committed bigamy with Mr. Z and the student; she was convicted and sentenced. Shortly after her release from prison, she was discovered disguised as a hospital nurse collecting subscriptions on behalf of an imaginary nurse supposed to be in trouble. In another district she incurred a hotel bill by fraud, was again convicted and sentenced. On the day of her release she telegraphed from a hotel to a gentleman in another city impersonating a lady friend of his resident elsewhere, saying she was in trouble in the city in which Jane was. The gentleman sent one of his family there, but the lady friend could not be found, and it was afterwards learnt she had never left her far distant home.

Fourth and Fifth Marriages and More Adventures.

Her next known adventure was to pose as a ward in Chancery who was to come into a large sum of money in a few months. A young gentleman who came to stay in the same hotel was told this by her; six days later they were married and returned to live with the youth's parents, with whom she became very popular. Whilst with them some wearing apparel which Jane obtained on approval was suddenly discovered to be on fire, but Jane was not suspected. By a fortuitous chance her whereabouts became known to the police, and she was arrested on a charge of bigamy with the youth, convicted, and sentenced to imprisonment. During this sentence she was temporarily transferred to a civil hospital for operation, and there became acquainted with the names of various nurses and medical men. On her release from prison at the expiration of the sentence she garbed herself in nurse's uniform and assumed the name of one of the hospital nurses who had left. She telephoned to the hospital for a character, and received an excellent one. She went to a boarding house in nurse's uniform, but owing to her conduct and conversation the boarding-house keeper, believing her to be an adventuress, ordered her to leave. During her short stay in this house several sums of money were missed; she was suspected, but sufficient evidence to prove her guilt could not be obtained. She then went to another town and, impersonating a certain lady, put up at a hotel and made herself, as usual, generally agreeable. She called upon a philanthropic lady, alleging she was greatly interested in a poor widow and her children, and asked for the lady's assistance; she was left alone in the room a few minutes and when she had

AN OUTBREAK OF BACILLARY DYSENTERY IN A BOYS' SCHOOL.

BY W. E. FITZ-GERALD, M.B., CH.B. EDIN.,
DEPUTY M.O.H., SOUTHPORT.

THIS outbreak of bacillary dysentery was brought to notice by the notification of an acute case which occurred in a boarder at the school. In consequence of this the school was visited, and the following facts were obtained.

The School.—A boys' school containing 40 boarders, and having an attendance of about 150 day-boys. It consists of two large houses joined together; one house, where the classrooms are situated, is used almost entirely as a school-house, but has at the top a dormitory for six boys. The other is the headmaster's house, and in addition to the headmaster and his wife, the kitchen staff, &c., accommodates 36 boarders. Six rooms—three on the second storey and two on the third—are set apart as dormitories for the boarders. There is one w.c. on the second storey, with a bathroom adjoining. The towels used by the boys are hung up in the bathroom on numbered pegs.

Intercommunication between Day-boys and Boarders.—During the day both day-boys and boarders use a block of offices in the playground; and if a day-boy remains for meals, he attends at the dining-room in the headmaster's house with the boarders.

The outbreak began with a series of cases of mild diarrhœa lasting for a day or two, and only in one case was the boy ill enough to be confined to bed for more than two days. This case was the first to occur, and lasted for seven days, but was of a mild type. All cases amongst the boarders occurred in three dormitories, two on the second storey, on opposite sides of the central landing, and one on the third storey.

Sequence of Cases.

(1) *Amongst Boarders.*—The first case occurred on March 1st, the second and third on the 6th, the fourth on the 7th, and the fifth on the 9th. The first acute case giving a typical clinical picture of bacillary dysentery occurred on the 9th, another acute case commencing on the 11th. Two boys were already isolated in two dormitories on the top storey, one suffering from measles and the other a measles contact. There was an indefinite history of both having had slight diarrhœa, so they were included in the investigation.

(2) *Amongst Day-boys.*—On the 14th, a day-boy became ill with symptoms of acute dysentery. Daily lists of absentees were asked for from the headmaster, and in each case of absence the home of the boy concerned was visited in order to exclude the possibility of mild cases being undiscovered; as a result of this one boy was found to be suffering from diarrhœa which lasted for one night. Specimens were asked for from the doctor in attendance, but were not obtained in a form suitable for laboratory work. This boy has not been included in the laboratory report.

The order in which the cases occurred is shown in Table I.

* Acute cases with typical clinical symptoms.

Southport Organisms.—The strain isolated from the first acute case proved to be of the Flexner type, although it was also agglutinated by type Y serum; and this strain was recovered from the second and third acute cases.

The examination of fæces of the three clinical cases gave the bacteriological findings as shown in Table II. (A). Cases T. and E. showed very definite clinical dysenteric conditions, were seriously ill for a few days, but cleared up satisfactorily, while Case G., who was the last of the three clinical cases to develop the disease, was by far the most serious clinically; and several doses of anti-dysenteric serum were administered during the initial days of the illness. The examination of fæces from seven boys with a history of mild diarrhœa gave the bacteriological findings as shown in Table II. (B).

L.F. = Lactose-fermenting colonies. N.L.F. = Non-lactose-fermenting colonies.
A = Acid. — = Negative. AG = Acid and gas.

These two tables show that in this series of fæcal examinations of 10 cases, non-lactose-fermenting colonies were isolated in 7; of these, 2 proved in subsequent carbohydrate reactions and type-serum agglutinations to be non-dysenteric, leaving 5 strains which conformed in the sugar reactions, and also showed fairly constant agglutination results. In the agglutination tests the macroscopic method was used; and it was found that all the isolated strains of dysentery organisms agglutinated the Flexner type serum to a rather higher titre than the Y-strain serum, and that Shiga serum was consistently negative in all cases. These cases had all at some time recently, and previous to the development of the acute clinical cases, suffered from more or less transient diarrhœa.

TABLE III.

Cases.	Flexner-Y stock culture.	Southport organism.
R. F.	1 in 400	1 in 200

A. C.	1 „ 400	1 „ 300
P. S.	1 „ 300	1 „ 200

The blood serum from the seven mild cases gave results when agglutinated against *B. dysenteriæ*, Flexner-Y stock culture, and the "Southport organisms" as shown in Table III.

A Good Example of Moral Imbecility.

Unlike many a recidivist, Jane has, I believe, never excused her repeated offences by alleging they were the result of the severity of the initial sentences of imprisonment passed upon her; her early sentences, in fact, were conspicuous for their moderation. Her career is not the result of an indolent nature drifting more or less passively into crime as the easiest way of getting a living, nor is it the outcome of the gambler's prompting, which so frequently causes crime; it is the inevitable result of active criminal desires constantly urging and seeking opportunity for the commission of crime, and constitutes, I believe, a good example of moral imbecility. Jane is a "luckless pot marr'd in the making," and well might she say:—

> "They sneer at me for leaning all awry;
> What! did the Hand then of the Potter shake?"

She complies with the four requirements of moral imbecility as laid down in the Mental Deficiency Act, 1913. "A person who from an early age displays some permanent mental defect coupled with strong vicious or criminal propensities on which punishment has had little or no deterrent effect." From childhood she has displayed, as shown in this narrative, strong criminal and also vicious propensities upon which repeated punishment has had no deterrent effect, and it can be safely predicted never will have any deterrent effect. Her delinquencies have lasted for a period approaching 25 years, and no one would hesitate to say they will persist. If we accept Mercier's doctrine that crime is due to temptation or opportunity, the environmental factor or stress, acting upon the inherent or constitutional factor, temperament, then Jane's incorrigibility appears evident. The constitutional factor is chiefly at fault, the environmental factor being insufficient to cause habitual crime in a person of normal or approximately normal temperament, and there can now be no prospect of change in her inherent mental constitution. That she is a woman of some talent, ability, and cleverness cannot be gainsaid, but she lacks discretion and fails in the higher mental level—viz., wisdom "which enables a man to regulate the more important modes of conduct in the more important affairs of life so as to achieve success in his career" (Mercier). By her intelligence she is able to gain a certain position, which through her lack of wisdom she is unable to retain. The instincts of sex, acquisition, and exhibition are uncontrolled, and result in sex immorality, fraud, and theft, in the wearing of her hair in a long false plait, and in her exalted impersonations. The maternal instinct is defective, the social instinct which should express itself in a desire for companionship, in consideration for and duty towards other members of the community, is undeveloped, the praise or blame of others, their approval or disapproval disregarded, altruism absent, the moral sense lacking. In these and in her failure in life are seen Jane's permanent mental defects, to these are due her anti-social career. That certain markedly anti-social lives are due to grudge formation or other mental conflict at an early age appears to be generally admitted, and one has known persistent criminal careers due to this cause. I was unable, however, to trace any such in my interviews with Jane. This was not surprising considering her ability for deception, and bearing in mind also the years which would have elapsed since such formation could have arisen; but I have been prompted to record her history, even at a time when the interpretation rather than the description of mental conditions is sought after, in view of the importance of moral imbecility and its admitted medico-legal difficulties. Some witnesses in court appear to rest their diagnosis on the turpitude of the particular offence with which the prisoner is charged, others to consider that all criminals are moral imbeciles, others again seem to hold the opposite view and to deny its existence apart from co-existing intelligence defect. The pitfalls are, however, lessened that witness who only forms a diagnosis in con- ity with the statutory definition.

It is usually only in such flagrant well-established cases as Jane's that the medico-legal witness is likely to obtain a sympathetic audience at the trial. It is when the unfolding of the case shows that the risk repeatedly run is out of proportion to the sought-for prize—the latter being neglected when obtained—that the jury are likely to be persuaded that the crime is due to a mental defect.

A CASE OF MELANOMA OF THE CHOROID

By A. E. KEOWN, M.B. Belf.

SARCOMATA, such as described in the following case, usually originate near the optic disc and grow forward pushing the retina before them. I cannot find any account of choroidal melanomata not covered by retina or retinal vessels. This particular tumour was seen in the first instance by Mr. Parry Morton, of Dowlais, an optician, who has supplied me with the following note:—

> "W. T., an engine-driver, aged 62, came to me complaining of discomfort in the left eye. On the nasal side behind the iris was an orange-coloured mass of the size of a lentil seed as seen by oblique focal illumination. It appeared to arise from the ciliary body or thereabouts. The fundus oculi and disc were normal. I warned the man that he had a most dangerous growth, that he must go at once to an ophthalmic surgeon, and refused to supply him with glasses."

This was in mid-August. Four weeks later he was seen by the present writer.

The whole pupil area was then occupied by a pale orange-coloured mass except a small space on the temporal side. There appeared to be a minute perforation of the sclerotic close to the corneal margin on the nasal side, evidently corresponding to the point of origin. The previous day he had seen Mr. Tudor Thomas, of Cardiff, who wrote that the tumour was a melanoma. Next day Mr. R. S. McClelland removed the eyeball in the Merthyr General Hospital, the patient at last consenting to the procedure as the sight of the eye was destroyed. All the conjunctiva and tissue near the perforation was removed, but the socket was not completely cleared as it was considered that the origin of the growth so far forward rendered so radical a procedure unnecessary.

The Clinical Research Association reported as follows:—

> "The section shows a choroidal malignant growth which is a melanoma. The origin of the pigmented cells from one original pigmented layer of cuboidal cells is very well seen."

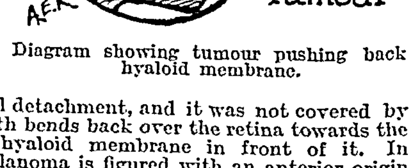

Diagram showing tumour pushing back hyaloid membrane.

The division of the eyeball into two nearly equal halves shows beautifully the origin of the tumour by a narrow base from the retina-free choroid between the ora serrata and the ciliary body. It did not therefore necessarily cause retinal detachment, and it was not covered by retina. The growth bends back over the retina towards the disc pushing the hyaloid membrane in front of it. In Haab's Atlas a melanoma is figured with an anterior origin but lifting the retina. In our hemispheres the retina can be seen in normal position. The microscopic slide shows typical cells, many of which contain much melanin.

The patient works with a powerful electric arc light suspended on his left and he has complained very much of the glare. He believes that the light had something to do with the causation of this trouble. The patient's opinion is of interest when one remembers the known effect of ultra-violet rays on the crystalline lens among men working in front of bright furnaces. The man is driving his stationary engine again. The stump is painless and can be rolled under the fingers. There is no enlargement of any abdominal viscus.

Dowlais, Glam.

Various Impersonations.

Shortly afterwards she obtained a situation in a hotel as bookkeeper, but being unsuitable was soon discharged; it was then found that she had obtained goods from local tradesmen, representing they were for the hotel proprietor's wife. She was arrested and sentenced to a short term of imprisonment on three separate charges. She then came under the notice of a social worker, and on discharge from prison went to a rescue home. From there she wrote to Mrs. X, representing the home as being the mansion of her guardian, Mr. Y, whom she alleged was pressing her to marry him, and as she only had £50 at hand—her fortune being tied up till she was 23—she felt at his mercy, but was determined to resist his attentions, and asked Mrs. X to take her as a paying guest. This arrangement, however, for some reason did not mature, and the rescue-worker, knowing nothing of this, and believing Jane to have been wrongfully convicted, recommended her to another lady. To this lady's distant rescue-home Jane went, and soon became popular with the inmates on account of her social talents and engaging personality. She told them she was about to be married to a young gentleman, who eventually arrived for the ceremony. He believed Jane to be single, and left abruptly on discovering her to be a married woman with children. It is noteworthy that whilst Jane was in this home money and other articles disappeared in an unexplained manner.

Arson and Theft.

Not long afterwards Jane arrived at a seaport, and stayed at a local hotel; a few days later fire broke out in one of the bedrooms and the place was gutted. The next day it was discovered that the cash-box and a sum of money were missing, and the police were informed. Jane, who had left the town, was traced, pleaded guilty to the theft, and received a short sentence of imprisonment. She was not charged with arson, but the events after Jane's arrival at the hotel, compared with previous episodes in her career, leave little doubt that the arson and theft were closely connected.

Bigamy and Various Other Deceptions.

On her release from this sentence of imprisonment she went to reside in the leading hotel of an important city, posing as a rich ward in Chancery; at this time she had plenty of money. She applied to the manager of a certain business, informing him she was a ward in Chancery who had run away from her guardian, and asked to be admitted into the business as a learner. She was employed at a small wage, and allowed the freedom of the place to learn what she could of its various branches. From the very commencement she showed a strong desire to introduce herself into the manager's home circle, eventually succeeding in so doing. In this gentleman's house she met a merchant, Mr. Z, who on first hearing of Jane warned the manager of the possibility of her being an adventuress, but within a few days of first meeting her he proposed marriage and was accepted. After about a fortnight's trial at the business she was dismissed, having shown herself incapable of steady application, and being a source of annoyance to the whole establishment. She would carry on prolonged conversations on the telephone with her alleged guardian, whom she stated was living at one of the hotels in the City. Ultimately she and Mr. Z married and lived together. Jane gave out to the neighbours that she was a Frenchwoman recently arrived in this country; to support this pose she spoke in broken English.

Her life with Mr. Z soon became unhappy; she involved him in debt with her reckless extravagance, and at one time he was paying rent simultaneously for three different houses she had taken in his name. One night while Mr. Z was lying awake he heard Jane talking in her sleep; she appeared to be holding a conversation through the telephone with Mr. Z's solicitor, inviting him to the house when Mr. Z would be out. The next day Mr. Z called upon his solicitor for an explanation, and was informed that that gentleman had not seen or heard of Jane for some months; Mr. Z was eventually satisfied that the whole thing was a hoax committed for some ulterior purpose. To those who know Jane there can be little doubt that her love of causing discord would be sufficient motive for this conduct. At one time when living with Mr. Z she sent for a doctor alleging ill-treatment by him. The doctor found no signs of this, but she appears to have threatened suicide. She was attended by a mental nurse and seen by an eminent authority on mental diseases; the latter said she was insane, and a danger to others, being devoid of any sense of right or wrong. She later called in another doctor, alleging serious illness; he found no physical ailment, but considered her hysterical. To this doctor she wove a romance that she was the illegitimate daughter of a lady, an admiral's wife, who had erred during the absence of her husband at sea, and that she was under guardianship. The doctor carefully observed her and considered her to be morally insane and wholly incapable of distinguishing between right and wrong. He also observed that she had already borne children, and on Mr. Z hearing of this they separated.

More Theft and Arson.

Soon afterwards Jane wore her hair in public as a long plait reaching below her knees, alleging so much hair was a cause of trouble and annoyance, but one day a lady taking hold of the plait to examine it found it came away in her hands; it had been merely pinned on to Jane's own hair. No reason at the time was assigned for this deception, and Jane, whilst admitting the facts, would give me none. Presently she applied for and obtained a situation in a business where customers' garments were sent. The day after her arrival she was detected cutting out the owners' names, replacing them by her own; she was dismissed, and later stolen clothing was found in her box at her lodgings. She next obtained a situation as companion to a lady under treatment for inebriety. The patient became worse, Jane apparently supplying her with intoxicants, and she soon had to be removed to an institution. Jane then set fire to the bedroom, stole a large quantity of the lady's clothing, saturated some of the other beds with water, lighted a large fire on the kitchen floor, and so terrorised the other servants that they all left the house together. She was arrested, charged with theft, and also of theft connected with the business aforementioned, and sentenced to a short term of imprisonment. She was not charged with arson, and although this is not the last reference that will be made to Jane's efforts at fire raising, I may here relate a somewhat parallel incident, when she was under the writer's care. For the purpose of better observation Jane was located in an association ward with other female prisoners. A dispute arose between them, and Jane seizing some papers set light to them and walked about the ward brandishing them and threatening meanwhile to set the ward on fire. The purpose of this seemed clearly to be to frighten the other patients into giving way to her.

Further Impersonations.

After her release from the sentence she applied for a post as probationer nurse at an institution, saying she was a married woman deserted by her husband. The superintendent and matron of the institution interviewed her and decided to help her. A few days later she wrote from a distance that she could not accept the post, as a doctor had seen her and informed her she was pregnant. Her appealing letter induced the kindly matron to travel and see her, secure lodgings for her, and inform her that a post would be kept open for her. Jane then notified her landlady that the superintendent was her guardian, and on the strength of this obtained credit for her lodging. Mr. Z at this time had obtained evidence of Jane's first marriage, his own marriage with her thereby cases had been cured. Alcohol injection was perhaps more successful, but occasionally failed, and then posterior rhizotomy was the only available treatment. He had been very disappointed with the results in this disease. Of 47 cases who survived and could be subsequently traced, only 20 were cured, and the remainder had either no or only very slight relief. This again, he thought, was due to the fact that the neuritis had spread into the cord before operation. In one case he had seen definite evidence of this at operation for causalgia following avulsion of the brachial plexus. Cicatrices of the scalp sometimes caused pain long afterwards. Sir William Thorburn had cured many such cases by reflecting the painful area as a flap and interposing Cargile membrane between the flap and the skull. For trigeminal neuralgia two methods of treatment were available: (1) injection into the ganglion, and (2) Hutchinson's operation of resection of the portion of the ganglion attached to the second and third divisions. The first method in his opinion imperilled the eye, whereas Hutchinson's operation did not, and he had not known any recurrence after that operation. Post-herpetic pain in the spinal nerves could not, in Sir William Thorburn's experience, be successfully treated by posterior rhizotomy. For tabetic pain he had now performed posterior rhizotomy on 70 occasions with a mortality of seven, which he thought was too high. Of the 63 patients who survived, 50 were cured or much improved, while in the remainder the improvement was very slight. In the treatment of sciaticas and brachial neuralgias Sir William Thorburn said it was his practice to expose the nerve from end to end, and he had thus been able to discover and remove the cause in a large number of cases. On the whole, however, he regarded these cases as unsatisfactory, since most of them had already been treated by hydro-, electro- and other therapies, and only came to the surgeon when these had failed. In conclusion, he said that quite a considerable number of persistent neuralgias were due to spinal tumours, which were overlooked in the operable stage.

Discussion.

Dr. GORDON HOLMES said it was commonly taught that lesions of the central nervous system did not cause pain, but this was abundantly disproved by war experience. Injury to the tracts in the spinal cord undoubtedly caused pain. He had seen a case of tuberculous sclerosis with intense pain; the man was operated on by Mr. Sargent and section of the tract was curative, although the man subsequently died of generalised tuberculosis. Again the posterior inferior cerebellar syndrome was associated with pain in the opposite fifth-nerve distribution. Pain was common in pontine and mid-brain lesions and even in lesions as high as the thalamus. Pain in syringobulbia was often confused with that of ordinary trigeminal neuralgia, and cases of this disease had been needlessly submitted to alcohol injection and gasserectomy.

Dr. S. A. KINNIER WILSON said he was sorry that no reference had been made to metatarsalgia. He had successfully treated three of these cases by alcohol injection. He asked Dr. Harris whether he had found the spasmodic movements associated with "tic douloureux" disappeared after alcohol injection, and Sir William Thorburn whether he recommended posterior rhizotomy for the generalised lightning pains of tabes.

The PRESIDENT said that his experience of posterior rhizotomy had been disappointing, especially where it was performed for causalgia. The only hope for these cases was to deal with the nerve at a high level at an early stage. He quoted one case of causalgia in a phantom hand. The man was wounded in 1918, and came to him in 1920, after numerous operations had been performed, for intense pain in a phantom index finger and thumb. The brachial plexus was exposed by operation and 80 per cent. alcohol injected into the nerve trunks. On the assumption that the pathetic nerves were involved he had dissected coats off the subclavian artery and also resected the ramus communicans from the first dorsal nerve to the sympathetic trunk. On the next day a contracted pupil and enophthalmos proved that the sympathetic nerves had been sectioned, but the pain was no better. He then performed posterior rhizotomy with division of the postero-lateral tract on the opposite side to a depth of 1 mm., and this was curative.

Reply.

In reply, Dr. WILFRED HARRIS said that the movements in "tic douloureux" were of two sorts—those brought on reflexly by the pain and a chronic facial spasm. The former was cured by alcohol injections of the ganglion, whereas the second was unaffected but could be abolished by alcohol injection of the facial nerve.

Sir WILLIAM THORBURN said that his posterior rhizotomies were performed for definite gastric crises and not for generalised tabetic pains.

SECTION OF LARYNGOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Nov. 4th, under the presidency of Sir WILLIAM MILLIGAN.

Laryngo-Fissure for Epithelioma of a Vocal Cord.

Among a numerous series of interesting cases the chief discussion took place on one presented by Mr. E. D. D. DAVIS, the patient being a comedian, aged 46, on whom the exhibitor performed laryngo-fissure for an early epithelioma of the right vocal cord, but without removing the ala of the thyroid cartilage, and the right vocal cord excised. The patient had a rise of temperature for three or four days following the operation, but within three weeks he had left the hospital with a normal temperature and the wound completely healed. Five weeks after operation, however, a superficial abscess developed over the right thyroid ala as a result of perichondritis.

Sir STCLAIR THOMSON agreed that the man had been left with a satisfactory roomy glottis. The speaker favoured removal of the thyroid ala in every case of this type. He had done so systematically since 1917, since when he had carried it out in 15 cases, 14 of whom were still alive. One had had a recurrence, and had had partial laryngectomy done, from which he had recovered well. In two patients out of 50 there was a little stenosis, with stridor on hurrying or going upstairs, and in those the thyroid ala was not removed. Taking away this ala had the advantages that, instead of leaving a bare cartilaginous surface, with only perichondrium on its outer side—a cartilage which might necrose—a fleshy inner surface was left on the larynx, which healed up quicker than did the thyroid cartilage. Before he started to remove the thyroid ala he had an old gentleman patient who developed bronchitis almost at the same time as the laryngo-fissure was done, and the wound broke open. A tumour the size of a cherry appeared in the anterior commissure which was found to be an enchondroma. He was, however, still well five years afterwards. That was a trouble which might occur from leaving the thyroid ala.

Mr. W. ROSE said it had been his practice to remove the thyroid ala ever since it was recommended by Dr. Lambert Lack, and his experience had been entirely favourable; the ala could be removed at the same time as the growth.

Mr. DAVIS, in reply, said it had been his original intention to remove the ala, but it was such an easy operation and the airway was so good that he thought it was unnecessary. He had since regretted that he did not remove the ala, as the patient developed perichondritis five weeks after the operation.

Mr. HERBERT TILLEY related a remarkable case in which Dr. E. R. Morton's treatment of cross-fire X rays was successfully employed. A year ago a man had been operated upon for extensive malignant growth of the larynx, therefore the question to be decided was whether partial laryngotomy or laryngo-fissure should be done. There was very distressing stridor. It departed from the house the contents of a missionary box which was in the room were missing.

Somewhat later Jane telephoned to a gentleman holding an important position, claiming to have known him previously and mentioning many of his relations by name. He met her, and found her well-informed concerning his people. Subsequently she lunched with him and had rides in his motor-car. One evening when dining with him she feigned sudden illness and was conveyed to her hotel in his car. On inquiring as to her condition the following day he found Jane up, and she informed him she had to return to London at once to see a specialist. Instead she called up the widow of a well-known man on the telephone, and with a false story of being pestered with the attentions of an officer obtained a visit at her hotel from the lady. Jane in conversation, as proof of her genuineness, mentioned the names of people known to her visitor, eventually obtaining money from her sufficient to pay her hotel bill and buy a ticket for a long railway journey. A gold watch, alleged to have been her mother's but actually stolen from a hotel, she pressed upon the lady as security. After a short absence from this city, during which she obtained money by false pretences elsewhere, she returned; being arrested for stealing articles from the hotel she was sentenced to imprisonment. On her release she married a gentleman, who eventually left her after settling up various debts she had incurred as his wife. Still later she was convicted for unlawfully wearing a military decoration, and since then has served other sentences of imprisonment for fraud and stealing. In connexion with the latter charge it may be mentioned that she obtained a situation as matron in an institution and when dismissed for dishonesty a considerable quantity of the property belonging to the institution was found in her boxes.

Characteristics Noted when a Prisoner under Observation.

I may now add a few of Jane's characteristics whilst under observation. Prison regulations to a certain extent limited her literary output, but in her letters to acquaintances, to myself, or to the officers, an elaborate style and consequential phraseology were used which she evidently considered were the necessary accompaniments of a superior education; the writing itself was good, neat, and legible. Throughout her career Jane has been fond of introducing French words and phrases in her letters, usually inappropriate and mis-spelt, and although she would have had one believe her to be a linguist, in reality she was not so. She showed such artistic ability that it was not unreasonable to suppose that with little effort a market might have been found for her work. She was described by an observant officer as being able to do anything with her hands. She was an excellent needle-woman when she liked, she could make artistic trifles from nothing more elaborate than paper and ink. She was capable of earning a good living had her abilities been coördinated with moral sense and stability of character. She did not impress one as being unduly vain, but she wrote letters concerning her extensive wardrobe and valuable jewellery, apparently hoping the officials would consider her a person of importance.

I have already said that Jane showed none of the artifices of the courtesan; indeed, she was at times rather untidy, but there was once a suggestion—which may have been erroneous—that her cheeks were tinted with the red dye from a book cover, a not infrequent method of decoration amongst female prisoners. Her affected airs of refinement and a somewhat exaggerated modesty were regarded as posing. She lied constantly and with much plausibility, for no adequate purpose. She could make mischief quietly, keeping herself in the background; she made efforts to play off one official against another—not always to gain anything herself thereby, but merely to create ill-feeling between them. On one occasion, in an attempt to cause trouble, she alleged that her wedding-ring was lost and seemed much put out about it, but some days later it was found in the book she was reading. I never saw her lose her temper—to have done so would have been out of keeping with her superior air—but she permitted herself to show some petulance at times. With other prisoners she would quarrel, subduing hardened offenders with her threats. She really preferred to be alone. As a hospital patient she would obtain medical extras, and then give them to other patients—not out of goodwill, but to create jealousy and discord amongst them. After being granted extra diet she would surreptitiously throw it away. She was apologetic when complaining of illness, but as her complaints were usually groundless her apologies lacked sincerity. As a matter of fact, she had enjoyed a fair measure of good health, had never been in an asylum, had never had any fits, and was not addicted to alcohol or drugs. She always considered herself the injured party in every dispute, but I have no reason to suppose she was revengeful.

I have before me some of her writing, which shows, perhaps unconsciously, the impression Jane wished to give others—i.e., that she was a brilliant and vivacious woman. I believe, however, that she has no clear insight into her own mental condition; she realises that her ability is largely responsible for her crimes, but does not appreciate that she is lacking in moral sense. She is an extremely painstaking and industrious woman when employed at work she fancies, but the ordinary routine work of everyday life, whether in prison or at liberty, she scorns. Even should she so desire, she can make no permanent friends, the regard of her fellows is soon destroyed by her conduct and deceit; indeed, she never seems to have made any effort towards true companionship. She told me that as a child she was not interested in her fellows, did not care for games, nor concern herself with dolls, but spent much time in reading. There is nothing in her history to suggest, nor could I detect, any genuine affection for any individual. That she desired sexual relations must be deduced from the frequency with which she sought men's society, which Jane herself stated was forced upon her by economic conditions, but this contention is not supported by her history. She attributes her criminal career to perverse sexual practices with her husband, in which she was made to take a part some considerable time after their marriage. This might be interesting were it true, but her delinquencies had already begun some years before the alleged occurrences took place.

Jane never seems to have had any genuine maternal affection, nor to have taken thought for her children's welfare, but to have left them to the care of others at the earliest opportunity. I have no evidence that she was at any time actively and directly cruel. Real gratitude was unknown to her, kindness she repaid with deceit; she was always unreliable. That she understood something of human nature is clear from her history and also from episodes in her prison life. That she could exercise a patient ingenuity and much industry in formulating and carrying out her schemes was also evident. That she could easily deceive people ignorant of her career is not remarkable, but I have reason to know she was successful in deceiving even when her full history was known. She has been described as an adventuress, and as is usual with this type she "worked" alone. That she loved adventure, change, excitement, was reckless as to the risks she ran, and regardless of consequences is clear; that the temporary success her audacity achieved was as heedlessly cast aside is also evident. She informed me she commenced stealing when at a convent school, taking fruit from the orchard trees, and was quite definite that she indulged in this in a more open and persistent manner than the other children. She also admitted that at this time she committed other trivial thefts, and it has already been related that she was dismissed from her last school for pilfering. Her sex delinquencies commenced at or about puberty; it is therefore possible to say that this and the acquisitive instinct were uncontrollable or uncontrolled from an early age.

together with other evidence of advanced arterial disease, in his opinion, contra-indicated operation. Mr. Sinclair also showed a man with an extensive syphilitic ulcer involving both sides of the neck. The Wassermann reaction was strongly positive. A similar but smaller ulcer was also present under the right axilla.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

The Use of Anti-Gonococcal Serum.

AT a meeting of this Society held at Liverpool on Oct. 21st, Mr. CARLTON OLDFIELD (Leeds), the President, being in the chair, Miss F. IVENS (Liverpool) read a paper on the use of anti-gonococcal serum as an adjunct to conservative surgery in gonococcal infections, basing her remarks on the results of its administration in 40 cases, in the majority of which salpingitis had been the prevailing feature. Nicolle's serum from the Pasteur Institute had been employed, administered: (1) by intraperitoneal injection during laparotomy; (2) by subcutaneous injection after dilution with normal saline; and (3) by vaginal serum packs alternating with packs of 10 per cent. salt solution mixed with 5 per cent. carbolic lotion. It was pointed out that the administration of salt solution at the time of serum injection diminished the incidence of anaphylactic phenomena. In the majority of cases the pus tubes were opened up and 20 c.cm. of serum injected into them or left in the pelvis. The tubes were not removed unless extensively damaged and the abdomen was closed without drainage. All the patients had made an immediate recovery and the results in cases of salpingo-oöphoritis, endocervicitis, and arthritis, and more especially in puerperal gonococcal infections, were excellent. A large number of cases followed up were found to be in good health, presenting a marked contrast to cases treated without serum. Three cases required further operation, but the possibility of re-infection was present. Miss Ivens considered that the results obtained warranted extended study with a reliable serum.

SOUTH-WEST LONDON MEDICAL SOCIETY.

THE first meeting of the session was held at the Bolingbroke Hospital, Wandsworth Common, on Nov. 9th, when Dr. Strickland Goodall gave a demonstration on the Rôle of the Electrocardiograph in Practical Medicine. He gave a brief account of the discovery of the heart currents, and then described rapidly the evolution of the electrocardiograph to the present time. After explaining the modern instrument and describing the various leads, he passed on to consider the physiological electrocardiogram, associated its different waves with activity in definite parts of the heart, and explained how these waves became modified in structural changes of the myocardium. Dr. Goodall illustrated this point with special reference to mitral stenosis, showing how the electrocardiogram gave an accurate picture of the pathology of the disease in any stage. He next demonstrated the analyses of some of the more important arrhythmias—auricular fibrillation, flutter, sinus arrhythmia, heart-block, extra-systoles, and so forth. After detailing the chief features of these, he described in detail the diagnoses of defects in the conducting system, demonstrating how lesions could be located in any part of the bundle system. Dr. Goodall concluded by pointing out a series of conditions which could only be diagnosed by aid of the electrocardiograph, and indicated how this instrument could be used for judging of the effects of drug and other treatment and of the general progress of a case.

ROYAL INSTITUTION.—The ninety-sixth Christmas course of juvenile lectures, founded at the Royal Institution in 1826 by Michael Faraday, will be delivered this year by Professor J. A. Fleming, F.R.S., on "Electric Waves and Wireless Telephony," and will be given on the following days at 3 o'clock: Dec. 29th, "Surface Waves on Liquids"; Dec. 31st, "Waves in Air"; Jan. 3rd, "The Telephone"; [illegible] 5th, "Electric Oscillations"; Jan. 7th, "Electric [illegible]"; Jan. 10th, "Wireless Telephony."

Reviews and Notices of Books.

THERAPEUTIC IMMUNISATION IN ASYLUM AND GENERAL PRACTICE.

By W. FORD ROBERTSON, M.D., Pathologist to the Scottish Asylums. Edinburgh: E. and S. Livingstone. 1921. Pp. 278. 15s.

IN the first part of this book a series of brief chapters deal with bacterial infection as the cause of disease, with the facts regarding immunity that bear upon therapeutic immunisation, and with the bacteriological methods to be employed. Clear description of the apparatus is given and the preparation of culture and test media is well described. Only an outline of the facts which bear upon therapeutic immunisation is essayed, the reader being referred for full information to the well-known works of Muir and Ritchie, of Hewlett and of d'Este Emery. There follows a presentation, systematically arranged, of the differential characters of bacteria which must be identified in investigations designed to apply therapeutic immunisation in particular cases. Under this system the author points out that important pathogenic bacteria have been excluded from the list because therapeutic immunisation would have little or no application to the treatment of the conditions with which they are associated. It is frankly admitted that the system of classification is provisional. A brief description is added of the methods to be employed in the clinical investigation of infections, and, in dealing with the practice of therapeutic immunisation, a useful warning is issued against the random use of stock vaccines. While allowing that these have their rational use, Dr. Ford Robertson points out that even autogenous vaccines, in the hands of those who do not know how to use them, often do harm. More than the last half of the book is taken up with two long chapters dealing with bacterial infections amenable to treatment by therapeutic immunisation and with the circumstances of such treatment.

It is difficult to review a book whose suitability for any particular class of readers must be in question. The ground covered by the first part of the treatise has been covered by many text-books. Generous reference to some of these is profuse in the volume, but if the author's intention has been to appeal to students, we feel that such a class of readers would do better to consult the works to which Dr. Ford Robertson refers. The latter part of the work advances views which in many directions will not receive general support. It is quite well that the views should be set down for discussion, but they must be considered tentative. Under the heading of diphtheroid bacilli, for example, Dr. Ford Robertson prints a paper which he had prepared seven years ago pointing to the pathological importance of these bacilli, which he associated ætiologically with conditions which are not usually considered to bear that relation. Chronic infection by diphtheroid bacilli, he says, occurs especially in diseases of the nervous system, including certain types of neurasthenia, acute toxic insanities, dementia præcox, general paralysis, and tabes dorsalis. In the latter two he admits that the infection is perhaps always associated with syphilis. We may grant that we have no proof that infection of the brain by the *Spirochæta pallida* is a complete explanation of all the characteristic phenomena of general paralysis, but we must still require a good deal more evidence than Dr. Ford Robertson produces before his conclusions can be adopted.

He is aware, however, that his work is in the nature of a challenge to other workers, for in a prefatory statement he says that "numerous facts new to science are recorded and many heterodox opinions are expressed which are not likely to be accepted without a fight." We think that the fight which he anticipates is sure to come, and in certain places he

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF NEUROLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Nov. 10th, Mr. PERCY SARGENT, the President, being in the chair. Members of the Section of Surgery had been invited to attend. A discussion on

The Treatment of Persistent Pain due to Lesions of the Central and Peripheral Nervous Systems

was opened by Dr. WILFRED HARRIS, who said that persistent deep-seated pain, if accompanied by failing health, would always suggest malignant disease. He considered the causes of pain in the peripheral nerve-endings, and rapidly sketched the various forms of disease of the nerve trunks, posterior roots and their ganglia, the fillet or thalamus which gave rise to pain.

1. *Peripheral Causes.*—Dr. Harris said that neuro-fibrositis might be traumatic or rheumatic. The former had not been sufficiently recognised. He had once been consulted by a farmer for pain across the lumbar region, which had persisted with occasional acute exacerbations for 10 years, after a fall. Examination revealed a tender spot, and the patient was cured by the injection of a few drops of strong alcohol into this region. Lateral scoliosis might be associated with similar tender spots. Such neuro-fibrositis appeared to be due to inclusion of sensory nerve-endings in areas of slight scarring resulting from rupture of muscle or tendon fibres, or as the result of a chill; pain thus produced might occasionally persist for years until the nerve-ending was destroyed by strong alcohol. Trigeminal neuralgia was, he thought, probably due to septic neuritis of dental nerve filaments in the jaw. It was commoner in women than in men, on the right side than on the left, and in the upper jaw than in the lower. It was occasionally bilateral. In the early stages remissions commonly took place, but they became less frequent as the disease progressed. For the relief of this complaint drugs were useless, and the choice lay between alcohol injection of the Gasserian ganglion or of one of the main trunks, and operation (either gasserectomy or division of the sensory root of the fifth nerve behind the ganglion). Dr. Harris believed that alcohol injection of the ganglion produced as permanent a cure as the operation of gasserectomy. It had the advantage of being available for bilateral cases for which double gasserectomy was not permissible owing to the jaw-drop that would follow. Chronic non-paroxysmal neuralgia of either the upper or the lower jaw appeared to be limited to women usually of 15–35 years of age. It might persist for years and differed from true "tic douloureux" in not being relieved unless total anæsthesia was produced, either by injection, neurectomy, or gasserectomy; whereas a light anæsthesia from partial injection of the nerve trunk was often sufficient in the latter complaint. Geniculate neuralgia sometimes followed facial palsy when accompanied by herpes of the auricle. Severe spasmodic pain in the neighbourhood of the auricle, the angle of the lower jaw, and the upper part of the neck might persist for weeks or months. American authors had described the cure of such cases by section of the "pars intermedia." Glossopharyngeal neuralgia was very rare, but might simulate "tic douloureux" in the character and persistency of the spasms and pain. Sicard had reported section of the nerve behind the mandible as curing three cases.

2. *Diseases of the Nerve Trunks.*—Dr. Harris said that tumours at the base of the brain or naso-pharyngeal growths might simulate trigeminal neuralgia for a time, by irritation of the nerve, but the development of anæsthesia or motor palsy of the fifth nerve, or pressure symptoms such as diplopia or Eustachian deafness, would clear up the diagnosis. Gummatous neuritis of the fifth nerve might be recognised by persistent non-paroxysmal pain with the development of anæsthesia, a positive Wassermann reaction, and rapid improvement under active anti-syphilitic treatment. The symptoms of cervical rib pressure, also far commoner in women, were often produced by a first thoracic rib, so that a negative skiagram would not exclude rib pressure. This was suggested by varying though persistent pain in the neck and along the inner side of the forearm with perhaps anæsthesia of the ulnar border of the forearm and wasting of the hand muscles. Causalgia was a common occurrence during the war, but very rare in civil practice. It was often due to very slight lesions of the nerve trunks, and could usually be relieved by free alcohol injection of the nerve trunk well above the site of injury.

3. *Lesions of the Posterior Roots or their Ganglia.*—Post-herpetic neuralgia occurred mainly in patients over 50 years of age, and was confined to the region which had been involved in the herpes. Dr. Harris had recently had some success from alcohol injection in the Gasserian ganglion where the pain involved the first division of the trigeminal nerve. For post-herpetic neuralgia of spinal nerves posterior rhizotomy was not always successful. Hæmatorrhachis was an occasional cause of pain in the spinal nerve distribution. As regards the pain of tabetic crises he invited the experience of surgeons.

4. *Central Sclerosis of the Fillet of Thalamus.*—Intramedullary growths and syringomyelia and syringobulbia occasionally caused pain; the posterior inferior cerebellar syndrome caused persistent trigeminal neuralgia.

5. *Psychalgias.*—These were legion. In many cases they might be recognised by their lack of anatomical distribution, but in some cases they were only recognised when treatment had failed to cure the supposed lesion. Dr. Harris gave two instances of this sort of pain.

A Different Classification.

Sir WILLIAM THORBURN referred to the difficulty in judging the effects of treatment of pain. There is no accurate means by which the degree of pain could be measured. The mental effect of prolonged pain often caused the recurrence of pain sometimes in another part, after the original pain had been cured. Thus Sir William Thorburn had recently seen two cases of pain due to cervical rib which had been cured by operation; the patients returned later complaining bitterly of abdominal pain associated wit floating kidney. Sir William Thorburn divided case into three classes: (1) those in which there was definite lesion, such as pressure on the brachia plexus; (2) cases where the lesion was less definit and was possibly situated in the posterior roo ganglia; (3) those in which there was no definit lesion and which he called neuralgia. In the fir class the only question was diagnosis, and earl diagnosis followed by prompt and adequate trea ment was curative. In certain cases, however, whe pressure had existed for a long time, a neuritis migh be set up which caused pain even after remov of the original cause. This explained the failure some cases of operation for cervical rib which h been too long postponed. In the second class case Sir William Thorburn included certain cases painful amputation stump. Some of these we cured by removal of end-bulbs, but a percentage cases remained where pain persisted after removal the bulb and several inches of apparently normal ner These cases were, he thought, due to an ascend neuritis, and in some of them posterior rhizotomy the only resort. In his opinion these bulbs were to sepsis, and did not occur if the nerves were sufficiently short.

As regards causalgia, resection and suture of nerve was not always curative. Sixteen of hi approval. The results he quotes are certainly striking; he has collected 12 cases in which this procedure was adopted with only four deaths, whereas of 52 women in whom marsupialisation was practised 22 died. The conclusion is also arrived at from a study of Beck's statistics that the best time to operate is the thirty-eighth week.

Dr. Schumann's book contains a clear and interesting account of the present views with regard to ectopic gestation and will well repay reading.

Symptomatology, Psychognosis, and Diagnosis of Psychopathic Diseases.

By Boris Sidis, A.M., Ph.D., M.D., Medical Director of the Sidis Psychotherapeutic Institute. Edinburgh: E. and S. Livingstone. 1921. Pp. 448. 21*s.*

Dr. Sidis was one of the first workers in America to use as a therapeutic measure the revival of lost memories, chiefly by means of hypnosis or hypnoidal states; this he calls psychognosis and he speaks with authority concerning the method. When he discusses other topics he arouses doubts as to how far his authority carries. He divides insanities into those of organic origin (organopathies) and those due to poisons or toxic products affecting the neuron (neuropathies). Having ruled out any psychological cause of insanity he classifies psychopathies (i.e., neuroses and psycho-neuroses) also in terms of neurons, speaking of "functions of which the personal consciousness is found on examination to have lost control by reason of neuron disaggregation and dissociation" (p. 100). *Mental* dissociation is a theory, useful in description or discussion; *neuron* dissociation, here presented as an anatomical fact, is a misleading speculation. Later on, when Dr. Sidis discusses aphasia and speaks of "the number and function of the systems of neurons involved" (p. 260), we cannot tell, even from the context, whether he is talking of pathological findings or purely imaginary processes.

On p. 319 he emphasises views which would be regarded by most psychotherapists as retrograde: "I must say once for all that they who try their ingenuity and fanciful symbolisation and mental conflicts in order to squeeze out some important meaning out of psychopathic symptoms in the present life adjustments of the patient miss the essential point of psychopathic states. Psychopathic symptoms are essentially meaningless." In many hysterias the present meaning and aim are so obvious that the casual observer tends to ascribe the symptoms to malingering, and one of the chief difficulties in treatment, which Dr. Sidis must surely recognise, is to bring about the patient's adjustment to present life.

In an appendix is reproduced a paper by Dr. T. W. Mitchell, from the Transactions of the Psycho-Medical Society, in which appear certain notes of interrogation which are not in the original; if they are interpolations by Dr. Sidis their origin should be made clear. An allusion to "medical dignitaries taking a regular bath in sexual filth" seems obsolete; the introduction in which it occurs is dated July, 1914, so that this is presumably not the first appearance of the book. The views presented in it were possibly worth consideration seven years ago, but psychopathology has advanced since then.

Diagnosis.

Diagnostik innerer Krankheiten in Tabellenform. Third edition. By Dr. A. J. Cemach. Munich: J. F. Lehmanns. 1920. With 53 tables and plates. M.15.

As the author points out in the preface to the first edition, the symptomatology of disease of the internal organs is so complex that the accurate diagnosis of a case requires not only a knowledge of the clinical aspects of a malady but also of the signs and symptoms of the diseases with which it may be confused. There is a very general feeling of need for a concise expression of the principal signs and symptoms of internal disease. Dr. Cemach has made an interesting attempt to achieve this object by setting out the signs and symptoms of the commoner diseases in tabular form. The book consists of 53 tables, each table being devoted to the enumeration and comparison of the classical signs and symptoms of the more important diseases affecting a particular organ. Thus Table VI. deals chiefly with affections of the stomach, which are divided into diseases and neuroses of the stomach. The symptoms, findings on physical examination of the epigastrium, condition of the tongue, motor activity of the stomach, its contents, vomiting, appetite, description of the fæces, other symptoms, and the general condition, are set down in columns as they occur in acute gastritis (simple and toxic), chronic gastritis, atony of the stomach, simple and malignant ulcer and stenosis; then follow the neuroses—namely, gastralgia, gastric neurasthenia, secretory neuroses, and nervous vomiting. In the last column of the table the most important fact or facts in diagnosis are stated for each complaint.

The author's method is to choose a type symptom-group for the diseases of each organ and to give a bird's-eye view of the variations in the components of the symptom-group that are characteristic of the more important diseases of that organ. Separate tables deal with certain important single symptoms, such as dyspnœa, hæmaturia, and ascites. Infectious diseases are dealt with separately. Within the limits that the author sets himself he succeeds in presenting his subject in a concise and useful form.

The Stages of Human Life.

By J. Lionel Taylor, M.R.C.S. London: John Murray. 1921. Pp. 377. 18*s.*

This book appears to have been written with the amiable design of helping other people to lead happier and more efficient lives by persuading them to study what they ought to do in order to keep healthy. But what the author has to say is so common-place and is set out with such obscure prolixity that we doubt whether he will achieve his purpose. He might well reconsider his intention to publish further volumes on the same topics.

JOURNALS.

Journal of Laryngology and Otology, September and October, 1921. Vol. XXXVI., Nos. 9 and 10.—In the September number Mr. W. G. Howarth discusses operations on the frontal sinus; he finds the intranasal operation useful in recent cases but unsatisfactory in those of chronic suppuration, and prefers to remove the floor of the sinus, together with the anterior ethmoidal cells, through an external incision, thus establishing free drainage into the nose; the anterior wall and the mucous membrane are left intact, and the wound is sutured.—Prof. F. Hobday describes the operation of stripping the ventricles as performed for vocal cord paresis in the horse.—Dr. W. S. Syme mentions a method of treating asthma by application of 10 per cent. silver nitrate to the bronchi through the bronchoscope; Mr. J. L. Aymard describes the use of a small electric torch placed inside the mouth to detect bleeding-points after dissection of the tonsil; and Dr. C. McNeil reviews the present state of the theory of asthma as an anaphylactic phenomenon.

The October issue contains an article by Mr. T. M. Hovell, in which he claims that the majority of enlarged tonsils in children are not diseased, and that in these cases the proper treatment is the removal of the projecting portion with the guillotine.—Sir StClair Thomson gives a short account of the usual site of origin of intrinsic laryngeal cancer.—Drs. P. and E. Watson-Williams describe a method of exploring the posterior ethmoidal cells; Mr. F. Holt Diggle and Mr. F. B. Gilhespy contribute an analysis of 20 consecutive cases of acute mastoiditis treated by B.I.P. and primary suture with very good results: and Dr. Neil MacLay relates a case of osteomyelitis following an intranasal operation for sinus-suppuration with eventual recovery.

seemed that all which could be done for him was to tracheotomise and leave him alone, but it occurred to him that Dr. Morton's cross-fire method might give some hope. Dr. Morton agreed to treat the case, and three months after the applications the whole trouble had disappeared from the larynx, the patient had easy breathing, and the skin over the front of the neck was as soft as could be wished.

SECTION OF ANÆSTHETICS.

THE opening meeting of this section of the Royal Society of Medicine took place on Nov. 4th under the presidency of Dr. H. J. SHIRLEY. It was devoted to hearing and discussing a report by Dr. H. E. G. BOYLE on his recent visit, as the representative of the section, to the first meeting of the Canadian Society of Anæsthetists at Niagara, and to the meeting of the American Society of Anæsthetists at Boston in June last.

Trans-Atlantic Methods.

A practice followed to a considerable extent was to give the patient, some time before the operation was to commence, ¼ gr. of morphine, 1/100 gr. atropine, and 300 c.cm. of a 4 per cent. solution of magnesium sulphate subcutaneously into axilla or groin. Very successful anæsthesias were witnessed with gas and oxygen. Some passed the gas and oxygen over paraldehyde. The idea underlying this preliminary preparation seemed to be that the effect of the actual anæsthetic was intensified, and less of the drugs was required. Patients undergoing operations under local analgesia assured Dr. Boyle that under operation they felt no pain. Should distress appear, the method was to pass, by means of a motor, ether into the post-nasal space.

At the Harlem Hospital, New York, Dr. Lombard gave ethyl chloride for tonsil and adenoid cases. He sprayed the substance on to layers of gauze until the child became "muzzy"; he then poured more on, and covered the area with a sheet of rubber in which is a hole the size of a shilling, thus converting the open into a partially closed method. During the actual operation a suction pump draws all the blood away into a bottle, thus preventing it being swallowed. At Niagara the Congress was a great success, owing largely to the untiring efforts of Dr. McMechan, and those of Dr. Johnston, of Toronto. Great importance was attached, said Dr. Boyle, in Canada to taking blood-pressure readings of cases, as giving very valuable indications as to the patient's condition. If the blood pressure remained persistently low for half an hour, the patient usually died in a few days.

In this connexion considerable interest attached to Dr. McKesson's three degrees of circulatory depression. The first degree is that in which there is a 15 per cent. increase in the pulse-rate without a change in the blood pressure: or a 10 per cent. decrease in blood pressure without any diminution in pulse-rate. The second degree is that of an increase of 25 per cent. pulse-rate, with a 10 to 25 per cent. decrease of blood pressure. The third degree, which is recognised as that of definite shock, is that in which the pulse-rate is 100 or more and is ascending, accompanied by a falling blood pressure, reaching as low as 80 mm. of mercury systolic, and a pulse pressure of 20 or less. By these readings the anæsthetist can warn the surgeon of oncoming shock with greater certainty than if he had only the quality of pulse to guide him as indicated by the sense of touch. If the third degree lasted more than 20 minutes, said the demonstrator, the patient was practically sure to succumb. The method was demonstrated on a case in Boston City Hospital. At Boston the tonsillar operations he saw were done with the patient in the sitting posture.

Dr. Boyle praised the hospitals he visited, their equipment and organisation, particularly those at Montreal, Toronto, and Boston. At Toronto he found Dr. Johnston at the head of a most efficient staff of administrators of anæsthetics, and the representative described many of the operations and methods he witnessed. There seemed a likelihood that Toronto would lead the world in establishing a Chair in Anæsthetics; should that be so, it would be a great satisfaction to find Dr. Johnston as its first occupant.

The report was followed by a discussion, at the end of which the meeting approved a message of fraternal greeting and gratitude to both the societies in the Western Hemisphere which were concerned in the cordial reception of Dr. Boyle.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

A CLINICAL meeting of this Society was held at the West London Hospital on Nov. 4th with Sir G. LENTHAL CHEATLE, the President, in the chair.

Mr. OSWALD ADDISON showed a case of Periosteal Sarcoma of the Femur in a young man under treatment with X rays. After three applications the tumour had markedly decreased in size. Mr. Addison referred to the notoriously bad results of amputation in these cases, and though he did not think X rays would prevent metastases, he thought this treatment preferable to operation.—Dr. LEONARD DOBSON cited a similar case under his care in which radium had been buried in the tumour in 1914. The patient had remained well since.

Mr. HOWARD STRATFORD showed a case of Myxœdema following X ray treatment after amputation of the breast for carcinoma. After a year's radiation of the scar and supraclavicular region signs of myxœdema had developed. The condition had been kept under control by administration of thyroid extract.—Dr. ARTHUR SAUNDERS thought that the X rays had in this case undoubtedly destroyed the secreting tissue of the thyroid.—Mr. ADDISON agreed and suggested that screening had not been efficient.

Dr. SAUNDERS showed an interesting series of cases illustrating thyroid insufficiency in children, the cases showing gradations from the mildest to the most severe types. He spoke of the almost miraculous results that could be obtained by the administration of thyroid in many cases of this kind.—Dr. SEYMOUR TAYLOR thought that the best method of administering thyroid was in the form of sandwiches of fresh sheep's thyroid. He thought that if tabloids were used the patients were apt to increase the dose without consulting their doctors, sometimes with harmful results.—In reply to Dr. VAUGHAN PENDRED, Dr. SAUNDERS said he thought that thyroid insufficiency was probably more common in children than was generally recognised, and that many fat dull infants were benefited by small doses of thyroid.

Mr. GILBERT CHUBB showed a series of cases of gunshot injuries of the face and head to illustrate the results of plastic operations for their relief. He pointed out in the case of reconstructive operations on the lips how rapidly a graft of ordinary skin would take on the red colour of the mucous membrane. He thought this might be explained by the great vascularity of the part. In dealing with defects of the cranium he favoured the use of the iliac crest for grafts.

Dr. J. BURNFORD showed a specimen of Streptotrichosis of the Lung in a man who died after nine months' treatment. Bronchiectasis had developed, but had improved under treatment with large doses of potassium iodide. The bases of the lungs were solid. The disease began with colitis, and Dr. Burnford thought the infection had probably been gastro-intestinal in origin. He alluded to the fact that streptotrichosis was more common than generally supposed. Dr. Burnford also showed a girl with Aplastic Anæmia. The blood picture was of the chlorotic type, and though the spleen was enlarged he did not consider the case one of true splenic anæmia. Infective endocarditis had been carefully excluded.

Mr. SANGSTER SIMMONDS showed a man with gunshot wound through the hip-joint in which ankylosis had occurred between the neck of the femur and the ilium above the acetabulum. The limb was adducted and progression difficult. Mr. Simmonds had removed the head of the femur and placed the neck in the acetabulum after division of the adductors. The limb was placed in the fully abducted position and firm ankylosis had resulted. The man could now get about with comparative ease.

Dr. L. S. BURRELL showed four cases to illustrate the results of artificial pneumothorax. The apparatus which was used in this operation was demonstrated.

Mr. NEIL SINCLAIR showed an Aneurysm of the Right Common Carotid Artery at its Lower End in a woman aged 61. No pressure symptoms were present, nor was there any indication of involvement of the innominate. X ray examination showed marked dilatation of the aortic arch; this fact, payments made by the class which uses hospitals. Whether the wage-earning and lower salaried classes prefer to pay for their treatment in advance when they are well or to wait until they require it, that remains to be determined. The present month witnesses a crucial experiment in medical providence. But the problem of voluntary hospital finance in London can be solved and the solution is brought one stage nearer by this admirable report.

◆

The Treatment of Persistent Pain.

Discussions on the subject of pain and its treatment will always command the attention of the medical profession. For one person who may stoically endure suffering there are a hundred others in whom the slightest twinge is enough to upset equanimity and to lead to the seeking of medical advice; and should the pain become persistent nothing calls for greater fertility of resource than its successful treatment. Cure, as always, depends on recognition of the underlying pathogenic process, and this in turn is based on ætiological knowledge and on ability to assess the temperamental or constitutional element in the individual concerned. For pain, being essentially a subjective phenomenon, can be gauged objectively only by its accompaniments, and if these are wanting we have no criterion to aid us, no touchstone to indicate unfailingly its unseen and intangible existence; we must either believe or distrust our patient. At the interesting and helpful discussion on the treatment of persistent pain, held at the Section of Neurology of the Royal Society of Medicine (see p. 1057), Sir William Thorburn emphasised the disadvantage under which the practitioner labours in having no objective measure for pain, but it is not clear that with it the task would be lightened. As the sufferer of old declared that "whereas I was blind, now I see," and cared nought for either pathological or therapeutic process, so the patient with symptoms of pain asks for no more than its relief or removal; in the absence of evidence to the contrary we must accept the actuality of his suffering, and if he says that with our treatment it has vanished we must just accept that too.

The contribution to the discussion provided by the opener, Dr. Wilfred Harris, who speaks with authority, was probably not intended to furnish a complete précis of the causes of persistent pain in diseases affecting the nervous system directly, yet it contained a sufficiently appalling number of conditions, each one of which is essentially painful, and for the relief of which skilful devotion on the part of the practitioner of medicine or surgery is required. Dr. Harris avowed himself an enthusiastic exponent of the method of alcoholic injection for many of these, ranging from the local points douloureux of neuro-fibrositis to the massive neuralgias of the trigeminal or the sciatic nerves. Through his hands some two or three hundred cases of trigeminal neuralgia have passed, and the failures constitute apparently only an insignificant minority. Sir William Thorburn, too, reported numerous cases of the same condition cured either by this method or by the surgical procedure advocated by Jonathan Hutchinson. From these two communications it may be gathered that the radical cure by gasserectomy is rather falling into desuetude; apart from its seriousness, it presents several disadvantages, one of which is its inapplicability to bilateral cases, at ast if the motor branch of the fifth is to be avulsed h removal of the ganglion. Be this as it may, tic douloureux has lost its terrors, and no one need ever again be driven to suicidal extremities, as has regrettably been the case on occasion in days gone by. Causalgia, another variety of persistent pain, largely the aftermath of the war, also received a considerable amount of attention. Here the record was possibly not quite so satisfactory, but on the whole we may learn that it, too, can be cured. Failure to realise the importance of the conception of ascending neuritis in this connexion probably accounts for a certain number of non-successful interventions. If alcoholic injection is utilised it should be made at several points well on the central side of the lesion, and if neurectomy is practised the proximal end of the divided nerve should be treated with alcohol injection also. There remain, however, forms of persistent pain in nervous disease that are unfortunately much less amenable to therapeutic procedures, notably the variety described as central pain, of which at the discussion Dr. Gordon Holmes gave a diagnostic description. He alluded to the kind that sometimes occurs in cord lesions, an account of which he contributed to the Osler *Festschrift*; in certain types of thalamic lesion, also, central pain is an only too conspicuous feature in the clinical picture. No really scientific method of treatment has as yet been evolved for such distressing cases, due as they are, if a recent theory of their origin be accepted, to release of function; in this respect they are akin to certain cases of release-phenomena on the efferent side, which similarly have proved to be peculiarly difficult to modify therapeutically.

For persistent pain originating in the proximity of dorsal root ganglia and not to be reached by alcoholic injection, the operation of dorsal rhizotomy received considerable support from Sir William Thorburn; in other, even more inveterate, cases, the President of the Section counselled the adoption of the operation of intramedullary section of the spino-thalamic tracts in the ventrolateral column of the cord, a procedure which can only be resorted to when other methods fail and when the outlook is in any event grave. Should this be unsuccessful, we suppose the neurological surgeon, daring though he be, will not advise destruction of the thalamus by electrolysis, or excision of the sensory cortex, nor need he, for as far as the latter is concerned the representation of pain in a cortical sensory area is somewhat doubtful. If pain is to be chased in this fashion from periphery to centre, inability to effect a cure can in the last resort be set down to the elusive nature of the sensation; the residual group of the topoalgias, or psychalgias, as Dr. Harris called them, can be made the receptacle of the failures. As useful as a discussion on treatment would be one devoted to the differential diagnosis of psychical from somatic algias. Various criteria and tests notwithstanding it is often a matter of great difficulty to distinguis the psychical from the physical, and accurate dia nosis demands considerable nicety and acumen. No contributor to the discussion at the Section of Neurology spoke of the treatment of psychalgia, from which one would not like to infer that neurology ignores painful mental cicatrices altogether. None the less the omission is noteworthy if it is to be taken as signifying indifference to a very large class of case of a really curable sort. Inability to ameliorate or relieve pain of organic central origin casts no discredit on neurological methods, for there is a limit to their applicability, but once diagnosis is satisfied with the non-organic nature of a particular pain its cure should be a matter of course. The lines to follow in such instances are doubtless familiar to the expert, but the practitioner would be grateful for help in this respect.

will be required to marshal the results of many years of industrious research very carefully if he is to emerge victorious.

FRACTURES IN GENERAL, INDUSTRIAL, AND MILITARY PRACTICE.

Second edition. By JOHN B. ROBERTS, A.M., M.D., F.A.C.S., Emeritus Professor of Surgery in the University of Pennsylvania Graduate School of Medicine; and JAMES A. KELLY, A.M., M.D., Associate Professor of Surgery in the University of Pennsylvania Graduate School of Medicine. London and Philadelphia: J. B. Lippincott Company. 1921. Pp. 755. £2 2*s.*

PROF. Roberts and his collaborator have produced a commendable work on fractures, achieving a judicious blending of the old and new. For example, whilst quite a number of the classical type of illustration showing the displacement of bony fragments due to muscle pull have been retained, these are effectively overshadowed by many excellent radiograms of actual fractures. The authors are in no doubt as to the efficiency of certain technical methods which they themselves follow, but they have generously quoted from others, and have illustrated and described at length many different methods of treating individual fractures.

In a preface they emphasise 26 "cardinal points," all of which are sound except perhaps the uncompromising statement that "joint fractures should not be kept immobile longer than one or two days." However, the bare dogmatism of this rule which would seem to imply a negation of the doctrine of rest, is modified in the section of the text where individual joint fractures are dealt with. The efficiency of what are termed "contour splints," moulded to the actual region, and made of plaster of Paris, is stressed. The writers, in common with other modern fracture surgeons, have little use for the conventional wooden splint. It is interesting to note that certain well-known wooden splints, such as the Carr splint for Colles's fracture, are condemned wholeheartedly.

One of the best sections is that dealing with fractures of the lower end of the radius; here the importance of efficient primary reduction, and the maintenance of the normal curvature of the radius, are emphasised. The chapter on fractures of the shaft of the femur is less happily conceived, although the various technical additions which have resulted from recent war experiences are discussed. Two useful chapters are those on Obstetrical Fractures and on Industrial and Warfare Fractures. In the latter, there is an excellent résumé of the modern early treatment of the co-existing soft part injuries with reference to the eradication of wound infection. The treatise as a whole is well planned and readable.

ZOOLOGY.

Outlines of Zoology. By J. ARTHUR THOMSON, M.A., LL.D. London: Henry Frowde, Hodder and Stoughton. Pp. 867. 18*s.*

Zoology for Medical Students. By J. GRAHAM KERR, F.R.S., Regius Professor of Zoology in University of Glasgow. London: Macmillan and Co. Pp. 485. 25*s.*

An Introduction to Zoology. By C. H. O'DONOGHUE, D.Sc., F.Z.S. London: G. Bell and Sons. Pp. 501. 16*s.*

OF these three elementary text-books that of Prof. Thomson has attained to the position of a seventh edition, which renders criticism somewhat superfluous, and also justifies the method of arrangement adopted by its author. In this there is no change; Dr. Thomson still gives a large mass of information, but a judicious use of small type draws attention from the less to the more important sections, and thus saves the elementary student from confusion.

Prof. Kerr, as the title of his book states, writes definitely for the medical student, and, therefore, perhaps lays more stress upon parasitic forms than he would have done in a book designed for a less specialised audience. The distinction is by no means overdone and other groups are treated quite adequately. A feature of this work is the large number of original illustrations drawn specially for Prof. Kerr, and certain of these, such as the nephridial organs (p. 309), renal tubule of vertebrate (p. 310), lung of fishes (p. 367), are usefully diagrammatic. In contrast with these, and excellent in their way, are elaborate drawings of the bird's feather (p. 428) and larval stages of Lepidosiren (p. 391), that South American dipnoid particularly associated with Prof. Kerr's important investigations.

While Prof. Kerr's text-book is written perhaps chiefly to meet the needs of the medical student, Dr. O'Donoghue's Introduction to Zoology is designed in the first place for the use of the science student of the University of London, though the author, who is a professor in the Canadian University of Manitoba, hopes that it will prove useful also to others. The greater part of the book is devoted to the anatomy and development of the frog, the dogfish, and the rabbit. The invertebrates (protozoa, hydra, obelia, lumbricus, and tænia) occupy only three of the 17 chapters. Dr. O'Donoghue does not ignore the general problems of zoology, such as variation, heredity, and so forth, but his manual differs from those of his colleagues in that he gives no bibliography to guide the student in extending his knowledge.

EXTRA-UTERINE GESTATION.

By EDWARD SCHUMANN, Lecturer on Obstetrics, Jefferson Medical College, &c. London and New York: D. Appleton and Co. 1921. With 71 illustrations. Pp. 189. Price 21*s.*

THIS book has been written to present modern views regarding this complication of pregnancy, with special reference to the opinions prevailing among American gynæcologists and obstetricians on the subject. After a short historical summary of our knowledge of ectopic gestation, Dr. Schumann discusses its frequency and ætiology, and registers his opinion that in the majority of cases the condition is predisposed to by the end-results of tubal inflammation or by the pressure on the tubes of neighbouring neoplasms. He calls attention to the discrepancies in the statistics relating to the relative frequency of tubal rupture and abortion, and regards rupture as occurring nearly twice as frequently as abortion. The situation of the tubal pregnancy is regarded as being the most certain factor in determining the mode of termination of the pregnancy; the chapter on the pathology of the condition is well written and there is an interesting account of three cases of interstitial pregnancy which the author has had the good fortune to observe.

The succeeding chapter is devoted to recurrent and abnormal forms of ectopic gestation and conditions simulating it. The author doubts whether an ectopic gestation has ever been diagnosed by palpation before any hæmorrhage has occurred into it, and with this statement we are inclined to agree. In the diagnosis of the condition he lays most stress upon some degree of metrorrhagia, together with pelvic pain. Operation is strongly advocated in every case, since it is difficult to be certain that the hæmorrhage has ceased in any given case and will not recur. There is, however, a good deal to be said for the opposite policy of not operating in all cases, for instance, of peritubal hæmatocele; and it is unfortunate that this side of the question is not presented in sufficient detail to enable readers of this monograph to form their own opinion. There is no doubt that many patients recover from a tubal abortion without operation, and there is no evidence that in such cases early operation presents any ultimate advantages to the patient as compared with expectant treatment.

In the treatment of cases of advanced extra-uterine gestation, in which it is impossible to remove the placenta, Beck's plan of leaving the placenta in situ and allowing it to become absorbed is quoted with the exudate. Where there is much lymph, drainage is unlikely to be of benefit for more than a few hours; where the infection appears virulent and there are few adhesions it would be dangerous to close the abdomen entirely. It is likely that in the future the surgeon will be guided by the naked-eye estimate of the clotting process and a microscopical examination of the fluid to determine the resistance offered to bacterial invasion. D. P. D. Wilkie has shown[1] that it is possible by a rapid microscopical examination of the peritoneal exudate performed in the theatre, to form an estimate of the resistance offered to infection, and thereby to judge the proper course to pursue. Such a proceeding might lead to a further advance in abdominal drainage, comparable to that achieved by a study of the mechanical factor of gravity which resulted in the adoption of the Fowler position. It is time for a collation of available experience.

MURDER BY MEANS OF BACTERIA.

THE rôle of bacteria as friends and enemies has not yet been fully estimated. Lempp, in a recent issue of the *Archiv für Kriminologie* (Vol. lxxiii., Parts 3/4), has an interesting article on the homicidal employment of bacteria, which is at present topical in view of certain proposals for the scientific development of warfare. Glancing at ancient literature, for instance Thucydides's account of the Athenian plague, and mediæval history, he pronounces, naturally enough, that these reports of pestilence spread through the action of enemies are in the great majority of cases merely fanciful. Just as baseless are the tales of aviators dropping bon-bons containing pathogenic cultures, or of laboratory workers contaminating water-supplies, which were recently given currency by, and perhaps often originated in, the sensational press. He states that on the German side such reports received for the most part immediate official investigation and discountenance. Probably the only authenticated instance of the use of pathogenic bacteria in warfare is, curiously enough, the practice of the warriors of the New Hebrides, of dipping the points of their weapons in marsh mud, which contains many tetanus spores. Equally scanty is indubitable evidence of murder by the means under notice; for probably there are but two properly recorded cases; and the second of these, that of the druggist and artist Hopf, did not go beyond an attempt. In 1914 Hopf was convicted of poisoning his first wife with arsenic, and of attempting to murder his third one by means of typhoid and of cholera germs. The latter infection was quite abortive, and examination of the culture in his possession showed it to have lost all virulence. The typhoid bacilli, on the contrary, were extremely pathogenic, having particularly high agglutination, a quality evident also in a strain isolated from the blood of an attendant, who also sickened, upon the wife. It was suspected that Hopf infected some of the entourage in order to give the impression of an ordinary small epidemic. Five days after poisoning his wife's food he began to take her temperature regularly: it duly rose two days later, but she recovered. He had caused her to make a will directing that her body should be cremated. The cultures—to the number of 30 within nine months—he had obtained from a private laboratory, asking particularly for the most virulent strains.

Accounts have appeared in American newspapers of murders, or attempted murders, in the United States by means of bacteria, the only specified kind being again typhoid bacilli; the statement even being made that it had been proposed to erect in Chicago—a city with one of the worst records for murder in the world—an institute expressly for combating this particular crime. However, the only documented example of a fellow to Hopf is that of a Dr. Pantschenko, who, bribed by a relative (by marriage) of the victim, murdered a rich young Russian by injecting, not bacteria, but a bacterial product—namely, diphtheria toxin. The injection was pretended to be of spermin, for therapeutic purposes, and the defence was an admission that the syringe might have been not properly clean, thus causing fatal septicæmia. Septicæmia was, indeed, the diagnosis first arrived at, by an independent medical man, while a second one took the condition for septic gangrene. The site of injection became bluish-black, the temperature rose to 40° C., and death followed in a week. There were two autopsies, the second only revealing the truth, by means of the discovery of a detachable grey membrane in the pharynx, of cardiac dilatation, and of peculiar thinning of the skin at the site of injection, appearances closely paralleled in ad hoc experiments on animals—namely, guinea-pigs—which also died on the seventh day. It was proved that Pantschenko had obtained diphtheria toxin from a laboratory, and also, on a previous occasion, cholera endotoxin and cholera bacilli, a poison suggested by the instigator aforesaid. Pantschenko was sentenced to 15 years' forced labour. The paper concludes with a review of current legal precautions against such crime, which seem in many countries to be altogether lacking, a state of things which its apparent great rarity does not wholly excuse.

THE WHITE LEAD QUESTION.

THE appearance at the present moment of a book[1] dealing with white lead is opportune, since the question is being keenly debated as to whether the use of this material in paints should be interdicted by civilised nations (see THE LANCET, Nov. 12th, a Report of the International Labour Conference at Geneva). The author, Mr. F. L. Cantineau, who is frankly and wholeheartedly a prohibitionist, presents his case as an advocate rather than as a judge; moreover, when dealing with the clinical aspect of the case, he suffers from not being a medical man. But we find here a useful summary based for the most part upon government inquiries and investigations carried out in many countries. All lead compounds, whether soluble or insoluble, are held to be poisonous; while, of them, white lead—i.e., carbonate of lead—is considered to be the most poisonous, and to claim most of its victims from among painters. Indeed, the number of deaths due to lead poisoning among painters is found to exceed that occurring in all other industries put together; nor does the damage cease there, since lead absorption, even to a slight degree, predisposes the victim to other diseases. We regret to find the skin placed in the forefront as a portal of entry for lead, the digestive system placed second, with the inhalation of lead dust third, since Dr. T. M. Legge has incontestably demonstrated that the order should be exactly reversed. Similarly, the author is at fault in speaking not unfavourably of the so-called electrolytic treatment of plumbism, which appears to possess no value. Mr. Cantineau is at his best when pointing out the almost insurmountable difficulties attending efforts to protect painters while working, for example, in private houses, from risk of lead poisoning, so long as paints continue to contain lead. The question as to whether illness among painters arises from breathing the vapour of turpentine and whether such illness may not have been ascribed to lead poisoning (an opinion recently put forward in this country by Sir Kenneth Goadby) is discussed by Mr. Cantineau at some length. Manufacturers of white lead, wishful to preserve their industry from destruction, have certainly attempted to make turpentine a scapegoat; the position is, however, difficult to accept when lead poisoning disappears, while paints containing no lead, but turpentine as before, are employed. The painter may be exposed to two risks; is that a reason for not abolishing one? If turpentine is toxic, we can turn our atten-

THE LANCET.

LONDON: SATURDAY, NOVEMBER 19, 1921.

Hospital Finance.

A STATISTICAL report of the ordinary expenditure of 112 London hospitals for the year 1920 has been issued during the week by King Edward's Hospital Fund for London, and can be bought[1] for 1s. 6d. This report is the latest of a series initiated in 1903, but first made public in 1908, and in it may be found, by anyone with eyes to read figures, a plain record of the cost of the voluntary hospital system as it exists to-day in the metropolis, and, incidentally, of the work done by the voluntary hospitals. The time is propitious for a comparison between pre-war and post-war conditions, and Mr. H. R. MAYNARD's crisp and lucid prefatory note sets out the total work and expenditure in 1920 alongside that in 1913; 1913 *being the last year when peaceful conditions* prevailed, and 1920 being the first year in which the fluctuations due to admission of naval and military patients have ceased to disturb civil hospital life. In brief, the position is this: Just over 1000 *more* beds are available in 1920, and of these nearly 700 are continuously occupied; there are 20,000 more in-patients and 50,000 more new out-patients; but while the increase in work inside and outside the wards amounts respectively to 7 and 30 per cent., the ordinary expenditure of the hospitals has leaped up in the seven years by 135 per cent. In other words, the metropolitan hospitals cost for about the same work two and a third times as much in 1920 as in 1913. It would be convenient still to regard this tremendous situation as an emergency, but it would be foolish and cowardly to do so. The situation must now be faced with a view to its long continuance, and faced straightly and squarely; and with this in view, we set down as shortly as possible in tabular form the main facts of work done and cost incurred in the ten different groups into which the voluntary hospital work in London naturally divides.

Group of hospitals.*	Average number of beds in daily occupation.	Average annual cost per bed.	Average number of days each patient was resident.	Total out-patient attendances (in thousands).	Average cost per attendance.
Larger General— With Medical Schools..	3867	£199	19	2661	*19d.*
Without Medical Schools	1079	£163	24	962	*14d.*
Smaller General ..	724	£156	23	561	*14d.*
Consumption	545	£143	55	126	*35d.*
Women's	258	£158	20	95	*19d.*
Children's	604	£152	24	467	*16d.*
Ophthalmic	220	£115	14	269	*14d.*
Epilepsy	321	£141	64	124	*19d.*
Cottage	304	£133	23	59	*9d.*
Lying-in	337	£119	15	133	*19d.*

* St. Bartholomew's Hospital and the Cancer Hospital are *not* included in this table.

It will be seen that the average annual cost per occupied bed at a large general hospital is in the neighbourhood of £160 when there is no medical school, or £200 when the hospital is also a teaching centre. The average cost per out-patient attendance is similarly in the neighbourhood of 1s. 2d. or 1s. 7d. We hasten to add that certain variable charges are not included in these figures, which are strictly accurate for comparison and only substantially accurate as totals. The cost naturally varies as between general and special hospitals of various kinds; in ophthalmic and lying-in hospitals, at which the usual stay is about a fortnight, the average cost is materially less; but within the several groups the variation in cost is very noticeable, and in the case of general hospitals with teaching schools varies from the norm of £200 to the extent of nearly £50 above and below. The report does not suggest that the lowest expenditure is intended to be taken as a model. It is not always that the lowest contractor's tender is accepted by the architect. But a primary object of publishing the comparative tables is that each hospital committee may reduce as far as possible *that part of the increase in cost which is not* represented by an increase in the quantity or quality of the work done. The Cave Committee, commenting on the striking differences in the expenditure between hospitals of like size and character, admitted that cost per occupied bed is at best an unsatisfactory criterion of value. The average period of in-patient treatment differs strangely from institution to institution, one teaching hospital in London keeping its patients on an average twice as long as another; and there is a very cogent plea entered by one hospital that its average weekly cost has increased for the reason that patients are transferred by motor ambulance to a continuation hospital in the country as soon as they can be moved, this transfer implying increase of cases at the hospital at their expensive stage. Granting the plea, added expense is just so much evidence of added efficiency and economical use of available hospital accommodation. Other allowances must be made in individual cases. At some hospitals articles are manufactured by direct labour, which at others are put out to contract; a number of London hospitals require patients who are not poor to provide certain articles of food; one hospital is staffed by a nursing sisterhood; paying beds at many hospitals bring up the expenditure.

But when all these sporadic differences have been given their due weight, we come back once more to the central and incontrovertible fact that the increased cost of living has hit the hospitals precisely in the same way as it has hit the private citizen, and for the public as well as the private consumer the reduced cost of living, of which so much has been heard and so little seen, had not taken effect at all during the year 1920. The largest London hospital speaks of reduction in the price of milk, but of *increased* cost in every other particular. Economy in the true sense is as urgent for the hospital committee as for the private citizen, but we doubt whether the average figure of £160 a year per occupied bed can ever again be substantially reduced. Outside London even that figure has in fact nowhere been reached. In some hospitals a more frugal regime may level down what a greater efficiency in others will level up; for efficiency will often imply more special departments, whatever their expense. Let this figure be accepted as the norm of expense and the solution of hospital finance be looked for where the Cave Committee indicated that it was to be found—namely, in indicated is of high value, and illustrates how, under enlightened management, insurance against disease may be made the means of curtailing the duration of illness and in many instances of preventing its occurrence. That this work is nationally important is self-evident; and we hope that the example thus shown will be widely followed.

[1] From Messrs. Spottiswoode, Ballantyne and Co., Ltd., 1, New Street Square, London, E.C.4.

In the September *Statistical Bulletin* it is stated that in 1910 the Metropolitan Insurance Company put into operation its measures of health propaganda, which were gradually extended, and now embrace over 13 million men, women, and children of the wage-earning population who are policy-holders; and it is added that at the end of ten years the death-rate has been reduced by more than one-fifth. Stated in added duration of life as measured by life-tables, this means a clear gain of nearly four years for every insured white male at age 10. The improvement in life prospects shown by these striking figures is remarkable, and there can be no reasonable doubt that the efforts made by the insurance company to protect and instruct insured persons have contributed materially to the result. It may be doubted, however, whether the effect of these efforts can be accurately measured, or whether they have borne a predominant part in securing the increased duration of life which has been experienced. In forming a final judgment on this point, it would be necessary to compare the life-table experience of the insured with that of the general population for the same period, to ascertain whether any change likely to affect results had taken place in the racial constitution of the insured, and to what extent sanitary and social amelioration had been shared by insured and non-insured. But although these considerations need to be weighed when an attempt is made to measure exactly the results of educational and nursing work, the value of the work itself is beyond doubt; and our judgment of its value must rest not solely on the imperfect indications furnished by such statistics as are forthcoming. In Sir Arthur Newsholme's words it is safer to rest our inferences and our administrative action, as guardians of the public health, on a careful balance of all available evidence, giving chief place to exact physiological and pathological evidence.

OVARIAN GRAFTING.

A COMMUNICATION by Prof. Th. Tuffier to the French Academy of Medicine on this subject, which was annotated in these columns last week, provides material for further thought. It is now generally conceded that the degree of menopausal reaction—that is to say, the severity of the symptoms accompanying the cessation of the periods—depends mainly upon individual factors, and in all cases of removal of the ovaries some portion of ovarian tissue should be conserved to ward off as far as possible the unpleasant symptoms which may attend the artificial menopause produced by complete removal of both ovaries. It is probably not true that in all such cases the artificial menopause is likely to be associated with more severe symptoms than those occurring naturally, nor does their severity appear to depend upon the age of the individual at the time the ovaries are removed. It was at one time imagined that the unpleasant results were due to some effect upon the nervous system, but that they are really due to the withdrawal of the ovarian secretion or hormone is now fully recognised. In order to prevent or to ameliorate the symptoms attending the complete removal of both ovaries, attempts have been made to transplant a portion of the ovary of the individual to some other part of the body—autotransplantation; or if a portion of the patient's own ovary is not available, a part of the ovary of another person is used—homotransplantation; and where this is impossible ovarian tissue has been transplanted from an animal of another species—heterotransplantation.

The results so far obtained have been very disappointing in most cases; the grafts either fail to take and quickly die, or if they survive for the time being they do not delay the onset of the menopause nor do they alleviate the symptoms. In a few cases, however, success seems to have been attained. Thus, in a case recorded by R. T. Morris,[1] in a young woman of 21 years of age both ovaries were completely removed by the angiotribe and two grafts from the ovaries of another woman were implantated in the posterior layer of either broad ligament; four months after the operation the patient menstruated again, and four years later she was delivered of a healthy child. In the discussion upon the case which took place, the interesting question was raised as to who was really the mother of the child. Tuffier, who has written largely on this subject, found a homograft to be of no effect, and further found that if an autograft—that is to say, a portion of the patient's own ovary—did not take, it usually disappeared in from six months to two years. In any case, his observations confirm those of other observers—namely, that after a period of some one to two years the transplantated portion of ovarian tissue appears to undergo a precocious senescence. The fact that homografts and heterografts are usually failures would seem to lead to the conclusion that there is some unknown antagonism between the tissues even of the same species as well as between the tissues of different species, and until this is in some way overcome success is very improbable. As a rule, the graft is implanted into the subcutaneous tissues, the subperitoneal tissue, or, as in some of Tuffier's cases, into the mammary gland. It would seem rather a dangerous practice to implant a portion of foreign tissue such as an ovarian graft into so active a gland as the mamma—a gland which is so peculiarly liable to the development of chronic inflammatory changes and malignant disease, and it will be interesting to see whether this site for a graft stands the test of time. Tuffier has obtained very striking results, and there can be no doubt that in all cases where it is found necessary to remove totally the ovaries in a young woman an attempt should be made to practise transplantation preferably with an autograft.

BACTERIOLOGY OF A SMALL FRENCH EPIDEMIC OF INFLUENZA.

A RECRUDESCENCE of epidemic influenza occurred in the Department of the Nord during the late spring of the present year and the *Revue d'Hygiène et de Police Sanitaire* for September contains an article by Breton and Grysez, from the Pasteur Institute of Lille, dealing with small epidemic foci in schools and barracks. In the case of the latter, it was the younger persons who were especially attacked, 80 per cent. of the cases coming from the 1921 class. The incidence rate was low, being only 1·85 per cent. in a total strength of 12,798 men. The clinical course of the disease was typical, the duration being on an average 5–8 days, and the chief complication bronchopneumonia; the temperature chart frequently showed a fall, after the first febrile period, succeeded by a second rise which was not attributable to any complication. The disease was benign in type, only one death being observed, due to a double bronchopneumonia. The writers contend that influenza is a clinical rather than a bacteriological entity, and that a variety of organisms may, at different times, be responsible for this syndrome. They base their opinion upon the different results which have been reported as to the presence or absence of Pfeiffer's bacillus in different epidemics. In the present series of cases they failed to find this bacillus either in films of sputum or in cultures. The predominating organism was a diplococcus or short streptococcus, the characters of which were considered by the authors to bring it within the enterococcus group. Blood cultures were negative. From complement-fixation experiments and the result of precipitation tests, which were positive, the authors finally concluded that this organism was of ætiological significance. [In criticism of this view it may be remarked that while the possibility of more than one infection producing

Nightshade.

THE series of cases of belladonna poisoning, notes of which have been appearing in our correspondence columns, brings before us two striking points in the toxic action of this drug. First, the capricious way in which it selects its victim; and, secondly, the way it spares its victim when it has brought him to death's door. Many of us have had experience at any rate of minor cases of poisoning such as that of a patient who, after the application of a belladonna plaster or of the liniment, has a widespread erythematous rash, or loses the power of accommodation so completely that he or she—it is generally, of course, a female patient—avers blindness. Dr. D. FIRTH and Dr. J. R. BENTLEY, in the case related in THE LANCET of Oct. 29th (p. 901), gave a more unusual method of absorption, a method which may well have been the cause of some of the unclassified cases of rabbit poisoning in the past. Atropine is rapidly absorbed and rapidly secreted, mainly by the urine, so that in this case the rabbit had probably taken the herb recently. On the other hand, patients, delirious from atropine, and even those who have reached the stage of the somnolence which follows delirium, frequently recover. The poison works itself off in sleep, and the patient who has seemed in danger wakes as from a dream. While the opium case frequently does badly, the patient who seems to have a corresponding depth of poisoning from belladonna does better than the medical attendant might expect. Of course, there are a certain number of deaths. In the Registrar-General's causes of death in England and Wales for the nine years 1911-19 102 deaths are recorded (accidental and suicidal) in which belladonna and hyoscyamus apparently played some part. Of recent years pharmacology has cleared up the active principles of the belladonna series, so that now we have little to consider but the isomers atropine and hyoscyamine, and the closely allied hyoscine or scopolamine. The two first stimulate the brain centres and paralyse nerve terminals, the last depresses both centres and terminals. The various species of datura are now recognised to owe their active properties to these alkaloids. Poisoning by any species of datura must be very rare in Britain, but ISHMAEL states, in the *Practitioner* of July, 1915, that in Cairo datura poisoning is so common that it occurs in frequency next only to acute alcoholism, and the symptoms are those of belladonna poisoning as regards the dilated pupil, the joking delirium, and the rapid recovery. He further writes, "I have not seen a fatal case, though many on admission were and remained for some hours on the verge of death."

BRITISH ORTHOPÆDIC ASSOCIATION.—The annual meeting will be held on Dec. 2nd and 3rd, at Liverpool, under the presidency of Sir Robert Jones. On Dec. 2nd, the morning session will be held at the Liverpool Medical Institution, where, at 10.30 A.M., a discussion on "The Late Results of the Treatment of Congenital Dislocation of the Hip" will be opened by Mr. H. A. T. Fairbank, followed by Mr. E. Laming Evans. Mr. C. Thurstan Holland will give a demonstration of radiograms of bone and joint affections. The afternoon session will be held at the Royal Southern Hospital, where Mr. T. R. W. Armour will give a demonstration of operations and cases at 2 P.M. On Dec. 3rd, at 9.30 A.M., a short paper on a series of endosteal tumours will be read by Mr. Harry Platt. A demonstration of endosteal tumours and bone cysts will be given by Mr. R. C. Elmslie, and a paper on Function in Relation to Repair in Bone will be read by Mr. D. McCrae Aitken. In the afternoon visits will be paid to Heswall and Leasowe Hospitals.

Annotations.

"*Ne quid nimis.*"

SURGICAL DRAINAGE.

THOSE who have followed surgical practice during the last 20 years have observed varying fashions in the methods of drainage, and even now there is no fixed rule of teaching. In our issue of Oct. 29th Mr. F. D. Saner judiciously discussed the first principles involved in the treatment of acute suppuration and recalled the fact that drainage benefits largely by relieving tension. On the general question of drainage Mr. Saner suggested that the prominence given to several very attractive but accessory lines of treatment such as antiseptics, tissue solvents, serums, artificial hyperæmia, has tended to divert us from consideration of the main principles. All surgeons of wide clinical experience will agree that rest and relief of tension are the most important points to attend to in a case of spreading inflammation. In dealing with large serous cavities, such as the peritoneum and pleura, other factors intervene. The main principles must be fulfilled, yet opinions as to the technique of abdominal drainage still differ greatly. It is not so long since any patient suffering from spreading peritonitis would leave the theatre with many rubber tubes projecting from the abdomen, like quills upon the fretful porpentine. This was the time when futile attempts were made to flush the peritoneal cavity free from infection by copious streams of saline solution.

Such methods, since they involved the neglect of the natural reparative processes of the peritoneum, were scientifically unsound and practically unsatisfactory. Later there arose the school which taught that the peritoneum could take care of itself in the presence of infection, so long as the main part of the gross exudate was removed by operation; this assertion was backed by experimental proof, which showed that drainage-tubes inserted into the abdominal cavity did not drain the main cavity for more than 12 to 24 hours owing to the formation of adhesions. Clinically it was found that the peritoneum could cause absorption of large masses of blood-clot in cases of ruptured tubal gestation. L. S. Dudgeon and P. W. Sargent showed that such clot was frequently infected by staphylococci. Further it was shown that even gross contamination of the peritoneal cavity, as evidenced by turbid fluid or lymph or even pus, could sometimes be successfully absorbed without drainage. But the question of closing the abdomen in the presence of infection is still *sub judice*. Mr. Saner voices a common view when he regards it as largely a matter of judgment whether the abdomen should be closed and the patient asked to deal with the remainder of the inflammatory process. If tubes are inserted, he says, it must be on the understanding that their purpose is not drainage, but an attempt to create a temporary track or line of least resistance. Possibly it is too great an assumption that the insertion of a tube merely relieves tension. There are cases of peritonitis in which much fluid is secreted and few adhesions form. Following perforation of a gastric ulcer there is often such free drainage from a pelvic tube for several days that no one can believe the fluid to come merely from the track of the tube. Experiments upon the formation of adhesions made upon normal dogs need to be checked from the experience of disease and surgery upon human beings. Peritoneal exudates vary greatly in their lymph-forming powers; ascitic fluid and some forms of inflammatory exudate do not tend to form limiting adhesions so quickly, and will continue to drain through a tube for a longer period than the prescribed 48 hours.

In judging how and when to drain the abdomen one must therefore consider the intensity of the infection, and the fibrin-forming or clotting power of indicated is of high value, and illustrates how, under enlightened management, insurance against disease may be made the means of curtailing the duration of illness and in many instances of preventing its occurrence. That this work is nationally important is self-evident: and we hope that the example thus shown will be widely followed.

In the September *Statistical Bulletin* it is stated that in 1910 the Metropolitan Insurance Company put into operation its measures of health propaganda, which were gradually extended, and now embrace over 13 million men, women, and children of the wage-earning population who are policy-holders; and it is added that at the end of ten years the death-rate has been reduced by more than one-fifth. Stated in added duration of life as measured by life-tables, this means a clear gain of nearly four years for every insured white male at age 10. The improvement in life prospects shown by these striking figures is remarkable, and there can be no reasonable doubt that the efforts made by the insurance company to protect and instruct insured persons have contributed materially to the result. It may be doubted, however, whether the effect of these efforts can be accurately measured, or whether they have borne a predominant part in securing the increased duration of life which has been experienced. In forming a final judgment on this point, it would be necessary to compare the life-table experience of the insured with that of the general population for the same period, to ascertain whether any change likely to affect results had taken place in the racial constitution of the insured, and to what extent sanitary and social amelioration had been shared by insured and non-insured. But although these considerations need to be weighed when an attempt is made to measure exactly the results of educational and nursing work, the value of the work itself is beyond doubt; and our judgment of its value must rest not solely on the imperfect indications furnished by such statistics as are forthcoming. In Sir Arthur Newsholme's words it is safer to rest our inferences and our administrative action, as guardians of the public health, on a careful balance of all available evidence, giving chief place to exact physiological and pathological evidence.

OVARIAN GRAFTING.

A COMMUNICATION by Prof. Th. Tuffier to the French Academy of Medicine on this subject, which was annotated in these columns last week, provides material for further thought. It is now generally conceded that the degree of menopausal reaction—that is to say, the severity of the symptoms accompanying the cessation of the periods—depends mainly upon individual factors, and in all cases of removal of the ovaries some portion of ovarian tissue should be conserved to ward off as far as possible the unpleasant symptoms which may attend the artificial menopause produced by complete removal of both ovaries. It is probably not true that in all such cases the artificial menopause is likely to be associated with more severe symptoms than those occurring naturally, nor does their severity appear to depend upon the age of the individual at the time the ovaries are removed. It was at one time imagined that the unpleasant results were due to some effect upon the nervous system, but that they are really due to the withdrawal of the ovarian secretion or hormone is now fully recognised. In order to prevent or to ameliorate the symptoms attending the complete removal of both ovaries, attempts have been made to transplant a portion of the ovary of the individual to some other part of the body—autotransplantation; or if a portion of the patient's own ovary is not available, a part of the ovary of another person is used—homotransplantation; and where this is impossible ovarian tissue has been transplanted from an animal of another species—heterotransplantation.

The results so far obtained have been very disappointing in most cases; the grafts either fail to take and quickly die, or if they survive for the time being they do not delay the onset of the menopause nor do they alleviate the symptoms. In a few cases, however, success seems to have been attained. Thus, in a case recorded by R. T. Morris,[1] in a young woman of 21 years of age both ovaries were completely removed by the angiotribe and two grafts from the ovaries of another woman were implantated in the posterior layer of either broad ligament; four months after the operation the patient menstruated again, and four years later she was delivered of a healthy child. In the discussion upon the case which took place, the interesting question was raised as to who was really the mother of the child. Tuffier, who has written largely on this subject, found a homograft to be of no effect, and further found that if an autograft—that is to say, a portion of the patient's own ovary—did not take, it usually disappeared in from six months to two years. In any case, his observations confirm those of other observers—namely, that after a period of some one to two years the transplantated portion of ovarian tissue appears to undergo a precocious senescence. The fact that homografts and heterografts are usually failures would seem to lead to the conclusion that there is some unknown antagonism between the tissues even of the same species as well as between the tissues of different species, and until this is in some way overcome success is very improbable. As a rule, the graft is implanted into the subcutaneous tissues, the subperitoneal tissue, or, as in some of Tuffier's cases, into the mammary gland. It would seem rather a dangerous practice to implant a portion of foreign tissue such as an ovarian graft into so active a gland as the mamma—a gland which is so peculiarly liable to the development of chronic inflammatory changes and malignant disease, and it will be interesting to see whether this site for a graft stands the test of time. Tuffier has obtained very striking results, and there can be no doubt that in all cases where it is found necessary to remove totally the ovaries in a young woman an attempt should be made to practise transplantation preferably with an autograft.

BACTERIOLOGY OF A SMALL FRENCH EPIDEMIC OF INFLUENZA.

A RECRUDESCENCE of epidemic influenza occurred in the Department of the Nord during the late spring of the present year and the *Revue d'Hygiène et de Police Sanitaire* for September contains an article by Breton and Grysez, from the Pasteur Institute of Lille, dealing with small epidemic foci in schools and barracks. [1] Medical Record, New York, May 5th, 1906.

The second part of the book is an excellent historical account of the fight to abolish lead poisoning among painters. France has led the way, for there the campaign started at the end of the eighteenth century, was active throughout the nineteenth, and became acute at the commencement of the present century. It finally culminated in France in 1909 in a law prohibiting the use of white lead, linseed oil containing lead, or of any material containing white lead for painting the inside or outside of buildings. A period of five years was given before the law should become operative, and the war intervened. The law was not enforced, and even now that the war has been over nearly three years, the difficulties of enforcing it have not been overcome. The difficulties arise from the fact that the manufacture of paint containing lead compounds is not abolished; such paints can still be used in the coachbuilding trade; meanwhile, inspectors cannot adequately control the use of such paints in private houses and other places. Clearly, if France intends to abolish the use of lead in paints employed on buildings, the law will have to be materially strengthened. No other country has yet proceeded so far. Regulations more or less stringent have been tried in Austria and in Germany, but they have failed to abolish the evil. The movement in Belgium, where regulations have also been tried, is discussed by Mr. Cantineau at some length, and the successful result of abolishing the use of lead paints on the State railways is quoted. The case with regard to Great Britain, where up to the present no action has been taken, is presented by relating the findings of the committees appointed to consider the matter; indeed, throughout this book the evidence presented to, and the conclusions arrived at, by these important committees are frequently quoted at length.

The remedy recommended is considered in the last part of the book. Here the conclusions of the author, who is an engineer, are of particular value. He maintains that substitutes such as zinc white and lithopone have been proved the equal, if not superiors, of white lead; and that supposed difficulties in their use are entirely imaginary. He shows, by quoting market prices, that both these materials to-day cost less than white lead. The sources of supply are looked into and declared to be adequate, so that increased demand should not inflate prices, but rather by calling more manufacturers into the field, tend to lower them. "If to-day white lead were suppressed," he asserts that "our houses would be painted as well as they are now and that we should not suffer in any way; and that very probably, after a period of 20 years, we should almost have forgotten the very existence of white lead."

PEDUNCULATED PERITONEAL TUBERCULOSIS.

THERE is a rare type of peritoneal tuberculosis, pathologically identical with that commonly found in cattle and known as Perlsucht, which is characterised by the formation of caseous or calcareous masses, surrounded by a fibrous capsule. In cattle these masses occasionally reach a considerable size and may become pedunculated by dragging on the underlying connective tissue. In a recent paper Dr. Henry M. Ray[1] reports a case of this condition in man in the belief that only two such cases have previously been recorded in medical literature, the first by Bizzozero in 1867, and the second by McCallum in 1901. Dr. Ray's case is that of a Polish labourer of 25, admitted to hospital with a five years' history of constipation, anorexia, and severe intermittent colicky pains, his later symptoms being a hacking cough, pain in the chest and abdomen, general weakness, and loss of weight. On admission the patient was acutely ill, the abdomen tender and rigid, and the ankles œdematous, auscultation showing numerous moist râles all over the chest. Thirty-six hours after admission he died, the post-mortem disclosing a mass consisting of a diffusely thickened and fused peritoneum and omentum, closely adherent to the recti muscles and fusing with the capsules of liver and spleen. The intestines were found to be thickly covered with subserous pedunculated firm nodules, varying in size from a pea to a large hazel-nut, with pedicles averaging 3 or 4 mm. reflected on to the nodules and merging into the serous coat of the intestine. The cortex of the kidneys contained multiple tubercles of the size of a pin's head, the cut surfaces of spleen and lungs being peppered with small nodules. Microscopical sections of nodules from the intestines showed typical tuberculous granulation tissue, with a distinct demarcation between the tuberculous process in the nodule and the underlying structure of the intestine. The parietal peritoneum also showed tuberculous granulation tissue with large areas of caseation, while perfectly typical tubercles with areas of caseous necrosis were found in lungs, liver, spleen, and kidneys. Although virulence tests were not carried out with emulsions prepared from the nodules owing to the fact that the tuberculous nature of the lesions was not suspected until the hardened specimens were subjected to routine histological examination, Dr. Ray suggests that the type of lesion found in his case and in the two described by Bizzozero and McCallum can best be explained on the basis of a specific reaction of the host to an infection with a tubercle bacillus, probably of bovine type, of a low degree of virulence. If this view of the pathology of the condition be correct, the nodules may perhaps be looked upon as representing the intestinal equivalent of the multiple benign so-called "sarcoid growths" of the skin, or nodular cutaneous tuberculomata, described by Darier and others.

ON THE MEASUREMENT OF RESULTS.

THE prudent rate-payer likes to see the goods delivered. For this and other reasons the fall in the general death-rate has been claimed by many different workers in the field of public health as evidence of their particular activity, and a salutary warning in this respect was given by Sir Arthur Newsholme in one of his American addresses.[1] He was himself once taken to task by Prof. Karl Pearson for associating as cause and effect the fall in the phthisis death-rate and the decrease in pauperism; Prof. Pearson alleged a similar correlation between cancer death-rate and expenditure per head on apples. Sir Arthur Newsholme rightly deprecated the quantitative assignment of credit for a given effort in public health work, when the circumstances leading to the desired result were multiform and complex. A recent issue of the monthly bulletins published by the Metropolitan Life Insurance Company of New York supplies an illustration of the need for such precaution. This company has, with perhaps one or two exceptions, a larger number of insured persons on its lists belonging to the wage-earning classes than any other society. Its work is carried out in a manner which is worthy of great praise. Not only is its experience carefully collated and the results from month to month and year to year made the subject of careful study by its extremely competent statistician, Dr. Louis Dublin, but the occasion is taken in each monthly bulletin issued to members and to the general public to give scientific information and instruction of high value on health matters. Not only this, but the company have issued leaflets and pamphlets on various health problems, prepared by experts on their respective subjects, and they have furthermore established an elaborate and almost nation-wide service of nurses, who are prepared, without cost to insured persons, to undertake nursing when acute illness occurs in the insured, and who also perform many of the functions of English health visitors in this country. The work thus briefly them to civil employment, where they would be self-supporting and not an additional burden on the public purse. We agree with Dr. Dickie in his regret that oto-laryngology was not officially recognised in the British army as a specialty during the war. It was not until the later stages of the war that special centres for ear cases were created and put in charge of recognised otologists, and then only after great insistence by the various consultants to the armies, equipment and organisation remaining highly inadequate. Neurological and eye cases could be referred to special hospitals at the base or in England, where expert service was available. Serious ear cases, on the other hand, were often sent to some small country hospital where they received no treatment by specialists. This should not happen again, and in order to secure an efficient organisation for the future a scheme should be worked out now, so that in war any patient requiring special treatment should be able to obtain it.

---

[1] American Journal of the Medical Sciences, August, 1921.

[1] THE LANCET, Oct. 15th, p. 833.

But, now that the war is over, the problem of chronic aural suppuration among the civil population is insistent. It is generally agreed that the large majority of cases of suppurative otitis recover completely if treated from the onset; the great cause of chronic otorrhœa, therefore, is neglect of the early acute stage, and the chief hope of improvement lies in the education of all concerned—parents, school-teachers, and medical practitioners.

EXPERIMENTS ON DOGS IN THE U.S.A.

A PAMPHLET printed in the Government Printing Office at Washington for the use of the Committee of the Judiciary contains a report of a section of the evidence before a subcommittee of that body given by Dr. W. R. Hadwen on the subject of experiments on animals. The subcommittee has been inquiring with regard to a Bill before the Senate, known shortly as S. 758, to prohibit experiments upon living dogs in the district of Columbia or in any of the territorial or insular possessions of the United States, and providing a penalty for violation thereof. The subcommittee consisted of two members only, Senator S. M. Shortridge, chairman, and Senator H. F. Ashurst, Senator Myers, the introducer of the Bill, being present at the inquiry, which appears to have been open to the public. Since apart from Dr. Hadwen's testimony the pamphlet contains only a number of letters from American medical men, deans of medical schools and the like, it is not evident whether any members of the medical profession from Great Britain are likely to lay views divergent from his before the subcommittee, but it should be said at once that Dr. Hadwen made no claim to represent his profession, or to give the views of British physicians or surgeons on the value of experiments on dogs or other animals. He described himself as president of the "British Union for the Abolition of Vivisection, which he believed to be the largest society of the kind in the world," and he frankly admitted that he had "eaten neither fish, flesh, fowl, nor good red herring for 40 years past," when questioned on his views as to the justifiability of killing animals for food.

Those familiar with Dr. Hadwen's expressed opinions will find nothing very novel in his version of them laid before the subcommittee. There is a familiar ring about a statement that "there is no Act of Parliament that a person cannot drive a team of horses through," or "I have no faith in and no sympathy with a government inspector whose whole vested interest lies in the practice of vivisection." This related, of course, to restrictions imposed in England. In criticising experiments attributed to American physiologists he travelled outside his country, and the subcommittee asked some pertinent questions as to the application of experiments upon animals to conditions peculiar to the United States. They were particularly inquisitive with regard to Dr. Hadwen's opinions on the desirability of experimenting on animals for the relief of the sufferings of animals. As to this Dr. Hadwen submitted that it should be sufficient to experiment on an animal when suffering in the ordinary course of things, not to seek a cure by infecting a healthy animal. His questioners referred especially to the bites of rattlesnakes and skunks, and as to the former, Senator Ashurst closed the discussion by saying, "Doctor, you live in England where there are no rattlesnakes, except in museums. I am not surprised at your answer; and I am not surprised that your friends applauded, because you know nothing about rattlesnakes." The incisiveness of some of Senator Ashurst's observations and the pertinent nature of his interrogations of the witness were evidently the result of professional experience. He observed with regard to the value of experiments on animals: "I am not a physician; I am a jack-leg lawyer, who knows when you are experimenting you would better experiment upon the pine than upon your mahogany. In this case I liken the pine to the dog and the mahogany to the human being." On the whole it appears unlikely that Dr. Hadwen has converted the American legislature to his views.

RETIREMENT OF SIR PHILIP MAGNUS, M.P.

WE understand that Sir Philip Magnus has decided not to offer himself for re-election as Parliamentary representative of the University of London. His letter of intended resignation has been received by the Unionist Association, but the opportunity thus given for the prompt selection of a candidate of this party should be equally convenient to those of other political thinking. Sir Philip Magnus has represented the University of London for upwards of 16 years, and has never forgotten that he was sitting for a constituency which has the largest percentage of medical voters in the Kingdom. He has been, throughout his period of service in the legislature, a consistent friend of what he believed to be the best interests of medicine, and his farewell letter to his political organisation includes a suggestion that is of universal application. He states that in the selection of a candidate to represent the University of London in Parliament regard should be had not only to his party views, "but also to his wide educational experience and to his detailed acquaintance with the requirements of members of the medical and teaching professions." All our readers know that to-day the interests of the medical profession require insistent attention in the House of Commons, and, having regard to the strength of the medical vote, it seems reasonable to suppose that Sir Philip Magnus, who has acted for so many years as a medical man for legislative purposes, will be succeeded by a Member of Parliament who is a qualified practitioner.

PERMEABILITY IN PHYSIOLOGY AND PATHOLOGY.

SOME five months ago an appreciative audience assembled under the auspices of the University of London to welcome Prof. H. J. Hamburger at the Royal Society of Medicine, and to hear him lecture on this subject. The address was of great intrinsic interest and was delivered in fluent and scholarly English; for Prof. Hamburger, like so many of his countrymen, speaks our tongue well, and his impromptu remarks were as apt as the more formal parts of his address. Further interest attached to the fact that Prof. Hamburger has himself taken such a large share in forming our modern theories on this subject of permeability. For a large part of his active life has been devoted to the study of this and allied subjects; his work began at a time when many of his hearers' parents were as yet unacquainted with one another, and when many of the remainder were yet at school; it is still in progress. We publish in this issue an almost verbatim copy of the address, which will be of especial interest to those who for various reasons were not able to hear his lecture.

The subject of permeability is of the greatest significance from both the theoretical and practical the clinical picture of influenza has every right to serious consideration at the present stage of our knowledge of the disease, it should constantly be borne in mind that the conditions essential for the isolation of Pfeiffer's bacillus are very precise, and that even in the 1918–19 epidemic some observers failed to find this organism, although its prevalence was a well-established fact. The organism found by the authors of the present paper would appear to be one of the streptococci so commonly noted in the pulmonary complications of influenza. Its characters do not completely correspond to those of the enterococcus of the fæces, although the possibility that this organism may become somewhat modified by a period of parasitism may well be granted.

DIPLOMAS IN OPHTHALMOLOGY.

ATTENTION is called in our news columns to the additional qualification in ophthalmology open to those who have obtained the F.R.C.S. Eng. Apart from this new distinction, there are already two diplomas in ophthalmology obtainable in England by examination. The first was instituted by the University of Oxford in 1910, the second by the Royal Colleges of Physicians and Surgeons in 1920, in response, as we are reminded in the current number of the *British Journal of Ophthalmology*, to a representation from the Ministry of Health, which desired to be able to select suitable medical practitioners to carry out ophthalmic work. For both diplomas candidates must be registered medical practitioners who have put in a year's attendance at a recognised ophthalmic clinic. For the Oxford diploma a term's attendance at a course of instruction at Oxford is essential. The London examination is divided into two parts, each being held twice a year, the first dealing with anatomy, embryology, physiology, and elementary optics, the second with ophthalmic medicine, surgery, and pathology. That the institution of this diploma meets a want is shown by the fact that for Part I. of the examination there were in July, 1920, 25 candidates, in January, 1921, 34, and in July, 1921, 31. For Part II. the corresponding figures were 11, 9, and 25. Of the 90 candidates who, so far, have presented themselves for Part I. 27 were referred; of the 45 who presented themselves for Part II. 6 were referred. As the *Journal* remarks, an indirect benefit to ophthalmology arising out of the establishment of the diploma has been the stimulus it has given to the study of the preliminary scientific subjects upon which the practice of ophthalmology ought always to be based. Special courses on these subjects are now being held at the Royal London Ophthalmic Hospital (Moorfields), at the Royal Westminster, and at the Central London Ophthalmic Hospitals.

FACTORS AFFECTING THE CONDITION OF THE TEETH IN CHILDREN.

THE Galton Laboratory for National Eugenics has issued a memoir (No. 7) by Mr. E. C. Rhodes on the Relationship of Condition of the Teeth in Children to Factors of Health and Home Environment. The memoir owes its inception to a report of a county school medical officer for 1912, and is an exhaustive statistical analysis of the dental records made in school medical inspections by the school medical officers of the county in question. The association of a number of factors with dental caries was examined and the personal equation of the medical officers who furnished the data received careful consideration. The author concludes that the data available as the result of inspections by school medical officers are inadequate for any useful statistical purposes, mainly on account of the lack of proper standardisation without which reliable comparisons cannot be made. It is, of course, realised that these data were not originally collected with a view to statistical treatment; if satisfactory statistical results are to be obtained standardised data collected under proper control would be necessary.

From the data actually examined, which form the subject of the memoir, it would appear that the degrees of association between the state of caries in the teeth of children of ages 12 to 14 years and their general health and home environment, are very slight, being roughly about 0·1 in the scale of the correlation coefficient where the range is from 0 to 1, zero being equivalent to absolute independence and 1 being equivalent to perfect association, between the two characters. This is an extremely small degree of correlation when compared with other relationships such as exist in the case of many physical characters between parent and child for which the numerical value is commonly 0·5. It would be of interest to ascertain whether any association exists between the state of the parents' teeth and those of the children, and if such an examination gave a result of the same order as those obtained for other physical characters—i.e., about 0·5—it would be a strong indication that the average bad teeth in a child are due more to bad teeth in the stock than to ill attention during growth. In connexion with this problem a certain amount of material has already been collected and it is hoped to pursue this part of the inquiry when further reliable data have been obtained. It is probable that much valuable information could be derived from the statistical examination of standardised data collected under proper control, and this aspect of the subject is one which will doubtless receive attention from the recently appointed Committee for Investigating the Causes of Dental Decay.

INCIDENCE OF HEREDITARY SYPHILIS.

Dr. P. C. Jeans[1] and Dr. J. V. Cooke have made a study of the incidence of hereditary, syphilis in St. Louis, based on an examination of the placenta combined with the Wassermann reaction in the cord blood in a series of 2030 infants, an almost equal number of whom belonged to the poor and to the well-to-do classes. Examination of the blood of 389 infants after two months of age showed that the proportion of cases of hereditary syphilis that could be diagnosed with certainty from placental examination alone was 27 per cent., while from the Wassermann reaction on the cord 63·6 per cent. of the cases could be recognised. The incidence of hereditary syphilis as determined by the combination of those methods was 15 per cent. in the coloured race, 1·8 per cent. in the poor of the white race, and less than 1 per cent. in the well-to-do classes. On applying these figures to the entire population of St. Louis, which according to the census of 1920 numbered 772,897, the writers estimate that the incidence of hereditary syphilis in that city was 3 per cent., of which the coloured population though numbering 69,854, or only 9 per cent. of the total, contributed approximately half the cases.

CHRONIC AURAL SUPPURATION.

IT is becoming increasingly recognised that the great prevalence of chronic middle-ear suppuration is accountable for an enormous amount of inefficiency among the population. This was, of course, particularly noticeable during the war, and Dr. J. K. Milne Dickie has some interesting observations to make on the subject in an article which appears in the current number of the *Journal of Laryngology and Otology*, entitled "Experiences of An Otologist in France, 1915–1919." He says that the wastage from this cause was enormous; numbers of soldiers running into thousands were constantly going from hospital to convalescent camp and back to hospital again, it might be for months at a time, receiving little or no treatment, and performing no useful work. He considers that it would have been much wiser to have discharged many of these men and to have put them to munition making, or even to have returned

NOTIFICATION OF TUBERCULOSIS, COMPARED WITH THE REPORTED DEATHS FROM THIS DISEASE.

By G. Lissant Cox, M.D. Camb.,
CENTRAL TUBERCULOSIS OFFICER, COUNTY OF LANCASTER.

At the present time considerable attention is being drawn to the unknown infective cases of tuberculosis which exist in all areas. It is generally agreed that the "known" consumptive is a much less dangerous person than the unknown, and also that, during the later stages of tuberculosis of the lungs, the largest number of the infective agent—the tubercle bacilli—is set free, so that each advanced case is more dangerous as a source of infection than an early one. If, therefore, as is the case at present, persons suffering from pulmonary tuberculosis are never notified, and die from the disease; and if, as is also often the case, notification is only made in the last stages of the disease, the attempts to combat the disease can only be partial and incomplete.

In the administrative county of Lancaster during the five years 1916–20 a very careful scrutiny has been made of all deaths from tuberculosis not notified under the Tuberculosis Regulations, and further, during a part of 1920 and 1921, a special inquiry was made into the reasons for non-notification in 163 consecutive cases. A summary of the results of this inquiry is given later in this article.

The total number of deaths from tuberculosis in the year ended Dec. 31st, 1920, and during the four preceding years, of persons *not notified* is given in Table I.

Table I.—*Deaths from Tuberculosis of Cases not Notified.*

	Pulmonary.	Non-pulmonary.	Total.
1920	177	122	299
1919	221	104	325
1918	303	137	440
1917	256	141	397
1916	270	147	417

The particulars of each death from tuberculosis have been carefully scrutinised in the public health department, so that, as far as possible, all deaths that do not properly belong to the administrative county have been excluded from these figures. Further, by arrangement, local registrars of deaths forward details of all deaths from tuberculosis, and these have been compared with the case notifications, enabling the particulars following to be obtained.

Three objects are served by a notification of a case of tuberculosis. First, the local public health authority is made aware of what may be, or will be, a case of infectious disease, and through the information received, will be in a position to deal with the same. Second, the person comes under the county special organisation dealing with the disease, and can then receive the advice and assistance of the tuberculosis officer, and such treatment as may be recommended will be given under the county scheme. Third, the examination of "contacts" is made possible, whereby early or other cases are discovered and may receive appropriate treatment. The 1920 figures are analysed in Table II.

As the total deaths in the administrative county in 1920 from pulmonary tuberculosis numbered 1323, the 177 *non-notified* fatal cases amounted to 13 per cent., as compared with 16 per cent. last year, 18 per cent. in 1918, and 16 per cent. in each of the years 1917 and 1916. It is satisfactory to note a decline in 1920 in the number of these non-notified fatal cases in the aggregate and in the percentage to the total pulmonary deaths.

There were also 375 deaths recorded in 1920 of persons notified as suffering from pulmonary tuberculosis which took place within three months of the date of notification.

Table II.—*Deaths from Tuberculosis in 1920 of Cases not Previously Notified.*

—	Cause of death.			Total.
	Pulmonary.		Non-pulmonary.	
	Primary.	Secondary.		
Deaths of persons with private addresses	130	13	108	251
Deaths of persons belonging to county area—				
In county asylums	15	—	2	17
In workhouses	11	—	4	15
In other public institutions..	7	1	8	16
—	163	14	122	299
	177			

Special Inquiry into 105 Deaths from Tuberculosis of Cases not Previously Notified.

As under the Public Health (Tuberculosis) Regulations, 1912, a medical practitioner is required to notify every case of tuberculosis to the local medical officer of health within 48 hours of diagnosis, it is important to ascertain the circumstances under which notification comes to be omitted. A period was taken extending from Oct. 11th, 1920, to June 30th, 1921, and during this time 163 of such deaths were recorded—80 pulmonary and 83 non-pulmonary. Of this number 58 occurred in public institutions, leaving for inquiry 105 deaths—45 pulmonary and 60 non-pulmonary. The result of the inquiries into the reasons for the non-notification of these 105 cases is shown in the following table:—

Table III.—*Circumstances of Non-Notification of Fatal Cases.*

—	Cause of death.		Total deaths.
	Pulmonary.	Non-pulmonary.	
Doctor in attendance shortly before death—			
1 week or less	3	8	24
1 to 2 weeks	2	8	
2 to 3 weeks	—	3	
Misinterpretation of Tuberculosis Regulations and notification believed unnecessary—			
Cases previously notified in another area..	5	1	16
Disease of long duration prior to compulsory notification..	1	—	
Temporary resident	—	1	
Cases known to tuberculosis officers*	7	1	
Attended by more than one doctor and notification believed to have been made by first practitioner..	9	8	17
Complicated cases presenting difficulty in diagnosis	6	19	25
Accidental omission to notify ..	5	7	12
No apparent reason for non-notification	4	4	8
Information not ascertained† ..	3	—	3
—	45	60	105

* Considerable doubt as to diagnosis in some of these cases.
† No reply received to inquiries.

Summary and Conclusions.

1. Amongst an estimated population of 1,730,929 in the administrative county of Lancaster, the number of deaths from tuberculosis in 1920 was 1710—pulmonary 1323, non-pulmonary 396.

2. The notifications of pulmonary tuberculosis numbered 2084, and non-pulmonary tuberculosis 968. About 70 per cent. of all new cases in 1920 were examined by the county tuberculosis officers *prior to notification*, these patients being sent for an opinion as to diagnosis and treatment.

3. The deaths from pulmonary tuberculosis not notified were, in 1920, 177, and non-pulmonary 122.

the clinical picture of influenza has every right to serious consideration at the present stage of our knowledge of the disease, it should constantly be borne in mind that the conditions essential for the isolation of Pfeiffer's bacillus are very precise, and that even in the 1918–19 epidemic some observers failed to find this organism, although its prevalence was a well-established fact. The organism found by the authors of the present paper would appear to be one of the streptococci so commonly noted in the pulmonary complications of influenza. Its characters do not completely correspond to those of the enterococcus of the fæces, although the possibility that this organism may become somewhat modified by a period of parasitism may well be granted.

DIPLOMAS IN OPHTHALMOLOGY.

ATTENTION is called in our news columns to the additional qualification in ophthalmology open to those who have obtained the F.R.C.S. Eng. Apart from this new distinction, there are already two diplomas in ophthalmology obtainable in England by examination. The first was instituted by the University of Oxford in 1910, the second by the Royal Colleges of Physicians and Surgeons in 1920, in response, as we are reminded in the current number of the *British Journal of Ophthalmology*, to a representation from the Ministry of Health, which desired to be able to select suitable medical practitioners to carry out ophthalmic work. For both diplomas candidates must be registered medical practitioners who have put in a year's attendance at a recognised ophthalmic clinic. For the Oxford diploma a term's attendance at a course of instruction at Oxford is essential. The London examination is divided into two parts, each being held twice a year, the first dealing with anatomy, embryology, physiology, and elementary optics, the second with ophthalmic medicine, surgery, and pathology. That the institution of this diploma meets a want is shown by the fact that for Part I. of the examination there were in July, 1920, 25 candidates, in January, 1921, 34, and in July, 1921, 31. For Part II. the corresponding figures were 11, 9, and 25. Of the 90 candidates who, so far, have presented themselves for Part I. 27 were referred; of the 45 who presented themselves for Part II. 6 were referred. As the *Journal* remarks, an indirect benefit to ophthalmology arising out of the establishment of the diploma has been the stimulus it has given to the study of the preliminary scientific subjects upon which the practice of ophthalmology ought always to be based. Special courses on these subjects are now being held at the Royal London Ophthalmic Hospital (Moorfields), at the Royal Westminster, and at the Central London Ophthalmic Hospitals.

FACTORS AFFECTING THE CONDITION OF THE TEETH IN CHILDREN.

THE Galton Laboratory for National Eugenics has issued a memoir (No. 7) by Mr. E. C. Rhodes on the Relationship of Condition of the Teeth in Children to Factors of Health and Home Environment. The memoir owes its inception to a report of a county school medical officer for 1912, and is an exhaustive statistical analysis of the dental records made in school medical inspections by the school medical officers of the county in question. The association of a number of factors with dental caries was examined and the personal equation of the medical officers who furnished the data received careful consideration. The author concludes that the data available as the result of inspections by school medical officers are inadequate for any useful statistical purposes, mainly on account of the lack of proper standardisation without which reliable comparisons cannot be made. It is, of course, realised that these data were not originally collected with a view to statistical treatment; if satisfactory statistical results are to be obtained standardised data collected under proper control would be necessary.

From the data actually examined, which form the subject of the memoir, it would appear that the degrees of association between the state of caries in the teeth of children of ages 12 to 14 years and their general health and home environment, are very slight, being roughly about 0·1 in the scale of the correlation coefficient where the range is from 0 to 1, zero being equivalent to absolute independence and 1 being equivalent to perfect association, between the two characters. This is an extremely small degree of correlation when compared with other relationships such as exist in the case of many physical characters between parent and child for which the numerical value is commonly 0·5. It would be of interest to ascertain whether any association exists between the state of the parents' teeth and those of the children, and if such an examination gave a result of the same order as those obtained for other physical characters—i.e., about 0·5—it would be a strong indication that the average bad teeth in a child are due more to bad teeth in the stock than to ill attention during growth. In connexion with this problem a certain amount of material has already been collected and it is hoped to pursue this part of the inquiry when further reliable data have been obtained. It is probable that much valuable information could be derived from the statistical examination of standardised data collected under proper control, and this aspect of the subject is one which will doubtless receive attention from the recently appointed Committee for Investigating the Causes of Dental Decay.

INCIDENCE OF HEREDITARY SYPHILIS.

Dr. P. C. Jeans[1] and Dr. J. V. Cooke have made a study of the incidence of hereditary syphilis in St. Louis, based on an examination of the placenta combined with the Wassermann reaction in the cord blood in a series of 2030 infants, an almost equal number of whom belonged to the poor and to the well-to-do classes. Examination of the blood of 389 infants after two months of age showed that the proportion of cases of hereditary syphilis that could be diagnosed with certainty from placental examination alone was 27 per cent., while from the Wassermann reaction on the cord 63·6 per cent. of the cases could be recognised. The incidence of hereditary syphilis as determined by the combination of those methods was 15 per cent. in the coloured race, 1·8 per cent. in the poor of the white race, and less than 1 per cent. in the well-to-do classes. On applying these figures to the entire population of St. Louis, which according to the census of 1920 numbered 772,897, the writers estimate that the incidence of hereditary syphilis in that city was 3 per cent., of which the coloured population though numbering 69,851, or only 9 per cent. of the total, contributed approximately half the cases.

CHRONIC AURAL SUPPURATION.

IT is becoming increasingly recognised that the great prevalence of chronic middle-ear suppuration is accountable for an enormous amount of inefficiency among the population. This was, of course, particularly noticeable during the war, and Dr. J. K. Milne Dickie has some interesting observations to make on the subject in an article which appears in the current number of the *Journal of Laryngology and Otology*, entitled "Experiences of An Otologist in France, 1915–1919." He says that the wastage from this cause was enormous; numbers of soldiers running into thousands were constantly going from hospital to convalescent camp and back to hospital again, it might be for months at a time, receiving little or no treatment, and performing no useful work. He considers that it would have been much wiser to have discharged many of these men and to have put them to munition making, or even to have returned

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Reappearance of Influenza.

ACCORDING to the October reports of the Board of Health a new wave of influenza threatens the city. Hitherto cases have been few and the course of the disease is mild, with a prevalence of intestinal symptoms, but with the recent sudden change of weather catarrhal manifestations appeared; cerebral cases have also been reported and practitioners have been warned. This time the younger part of the population is more affected, perhaps because older people have been immunised by almost universal epidemics during recent years.

The Rat Plague.

For some months the difficulties of everyday life in Vienna have been complicated by the appearance of swarms of rats and mice, apparently imported in consignments of wheat and grain from abroad. The considerable trade carried on with the Balkan States, and Eastern Europe generally, gives rise to danger of diseases communicable by these animals, and stringent precautions have been taken to avert disaster. Sanitary authorities have been instructed to pay special attention to the conditions of drains and sewers. It may be mentioned that the spread of influenza has also been attributed by some investigators to the spread of mice and rats.

The Problem of Doctors' Fees.

Owing to constant depreciation of the currency the medical profession is faced by a serious and hitherto unsolved problem. In a very instructive leaflet, published by the Medical Organisation, it is pointed out that the daily wages of carpenters, bricklayers, engineers, and shoemakers have increased from 100 to 120 times as compared with 1913, whilst their daily working hours have been cut down to eight. A number of other workers earn between 70 and 90 times their pre-war wages, whilst the prices of food and other necessaries have risen 120 to 200 times. These people can therefore obtain from 50 to 90 per cent. of the commodities they were accustomed to buy before the war. Doctors' fees, however, have not increased *pari passu*, and only quite lately have the public been asked to pay as much as 50 times the pre-war fee for medical attention. The Medical Organisation has now demanded a hundredfold increase of the original fees, and also stipulates that foreign patients shall be charged fees in their native currency. An English, Swiss, or Dutch patient charged 1000 kronen for each visit from a doctor would still only pay a fraction of the fees to which he is accustomed at home—1000 kronen being at present worth about two-thirds of a Dutch florin, 1¼ Swiss francs, or about 1*s.* 3*d.* But medical fees are considerably higher in their own countries, and such patients are expected to pay accordingly. For the country practitioners in Austria conditions are quite different; their payments are mostly made in "kind." For a consultation at the doctor's office the charge is 5 kilos of grain, or a kilo of meat, or half a kilo of butter or lard, or the equivalent in money. This arrangement satisfies both parties, as the conditions of peasant life are not much altered, but it is, of course, inapplicable to the towns. Panel doctors, and those holding appointments under private corporations, have also demanded an adjustment of salaries to meet the new monetary conditions. The result of all such increases is, however, only transitory; a man now earning 100,000 kronen a month is fairly well paid, but that is really equivalent to no more than a monthly salary of six or seven pounds sterling.

Statistical Data of Vienna Medical Students.

During the last university term 3228 ordinary students (including 450 women) and 127 extraordinary students appeared on the register of the medical faculty, being 35 per cent. of the total number of students at the university. For the present semester the number of first-year students to be admitted is fixed at 400. Last term very many nationalities were represented; the youngest students registered were 17½ years of age, and the number of ordinary students above 30 was 17. Students usually obtain their diploma of M.D. at the age of 25 or 26; over 600 qualified during the past semester. Foreign students can obtain diplomas only if they bind themselves not to practise in this country, but otherwise they are eligible to all house appointments or vacancies as internes and second assistants. About 28 per cent. of students were regular users of the cheap meal kitchen, chiefly supported by grants from the Anglo-American Relief Mission and the Red Cross Society.

Synchronous Combined Treatment of Metrorrhagia by Radium and X Rays.

At a recent meeting of the Vienna Gynæcological Society, Prof. Weibel reported the results of treatment of hæmorrhagic conditions of the uterus, including myomatous hæmorrhage, by a single (castrating) X ray dose, combined with radium application. The patient's abdomen is exposed for three to four hours to X rays, with a 3 mm. platinum or aluminium filter; meanwhile a quantity of 40–50 mg. radium is inserted into the posterior fornix vaginæ and left therein—well filtered—for 36 to 40 hours. Of the 160 cases so treated, amenorrhœa was at once induced in 33, 35 had only one more hæmorrhage, 47 ceased to menstruate after two months, and 8 after three or four months; the remainder had oligomenorrhœa, and 6 were altogether refractory. In younger patients oligomenorrhœa is produced by a dose which in older women is followed by amenorrhœa. As the latter often has disagreeable sequelæ (e.g., castration) it is advisable to aim at reducing the bleeding rather than causing it to disappear. A radium injury was only once noted—an extensive necrosis in the posterior fornix in a case of a patient with pernicious anæmia. In a series of 1510 women exposed for the same purpose to X rays during the years 1911–19, only 17 again became pregnant, with 24 fœtuses. Thirteen full-term children were born, and in nine cases abortion took place; the living children seemed to suffer no ill-effects from X ray treatment of the mother.

Nov. 3rd.

KING EDWARD'S HOSPITAL FUND FOR LONDON.

A SPECIAL meeting of the President and General Council of King Edward's Hospital Fund for London was held at St. James's Palace on Nov. 9th, when the EARL OF DONOUGHMORE, member of the President's Power Committee, presided. He read a letter from the Prince of Wales, in which his Royal Highness pointed out that under the Hospitals Commission the King's Fund had been constituted the central authority for London, and that this would involve certain duties which could only be properly carried out by reconstructing the committees of the Fund.

Lord STUART OF WORTLEY, the Chairman of the King's Fund Policy Committee, in presenting a report of that committee on the question of the reorganisation of the King's Fund, said that the proposals would involve no change in the Act of Incorporation. A resolution approving of the need for certain changes having been adopted, he presented a report of the Executive Committee on the conditions attached to Government grants to voluntary hospitals. This included the following resolutions:—

(1) That the President and General Council of King Edward's Hospital Fund for London have considered the conditions attached by the Treasury to the temporary assistance voted by Parliament to voluntary hospitals requiring that fresh money shall be raised pound for pound with the Government grants, and are of opinion that the application of this condition, which was not recommended in the report of Lord Cave's Committee, nor separately considered (much less expressly enjoined) by Parliament, will lead to great difficulties and probably to great

standpoints. Theoretically, because no problems of physiology, pharmacology, or pathology can afford to ignore it; practically because of its intimate contact with therapeutic problems. As examples of the former we may quote the theories of excitation and inhibition, conduction, fatigue, secretion and excretion, lymph formation and absorption, neutrality regulation, and many others; of the latter the fact that the problem of the treatment of spirochætal and trypanosome disorders is largely one of finding a means of successfully reaching the organisms by a curative agent after they have taken refuge inside the cells. Practical questions in connexion with sugar tolerance are also mentioned in the address. In the early days Prof. Hamburger did not find it at all easy to convince other investigators of the importance of permeability problems. It is different now. We want now to know more about them. The prominent place now given to the ionic interchange between corpuscles and plasma, known to many British physiologists as "the Hamburger interchange" or secondary buffering, in the regulation of the neutrality of the blood, is an example of the general acceptance of the far-reaching importance of cell permeability.

THE TOBACCO HABIT.

IN the evening lecture on Nov. 9th inaugurating the winter session of the Pharmaceutical Society of Great Britain, Prof. W. E. Dixon dealt with the subject of Drug Habits, beginning with the nearly universal habit of tobacco smoking. He gave a comparative analysis of the smoke from tobacco and opium burned under conditions similar to those which occur in smoking. The first column is the product of 100 g. of tobacco burned as cigarettes, the second of 100 g. of dross opium containing 7·35 per cent. of morphine.

Percentage product.	Cigarette smoke.	Opium pipe.
HCN	0·080	0·010
Pyridine	0·146	0·147
Nicotine	1·165	—
NH_3	0·360	0·395
CO	410 c.cm.	0
Morphine	—	0·016*

* Chandoo opium smoke contains 0·1 per cent.

Prof. Dixon continued :—

"Ordinary Virginian tobacco, from which cigarettes are made, contains, weight for weight, nearly twice as much nicotine as Manilla cigar tobacco. But when these two are burnt during smoking, the smoke from the cigar contains more than twice the amount of nicotine than that from the cigarette. During the slow combustion of a cigar, as in ordinary smoking, immediately behind the lit end is an area in which the water and other volatile substances in the tobacco condense; during the act of smoking a large portion of the nicotine at the seat of combustion is destroyed (50 per cent.), and the nicotine which finds its way into the mouth of the smoker is derived from the hot gases passing through this hot moist area in which the rest of the nicotine has condensed. The smaller the moist area behind the point of combustion the less likely is the smoke to contain volatile toxic bodies. A thin cigar or a cigarette will yield fewer of these products than a thick cigar, for the thin cigar or cigarette obviously permits a relatively greater cooling.

"The nicotine from the smoke of one cigar should correspond with the nicotine from that of 12 to 18 cigarettes. In practice it seems as if even less nicotine than this reached the circulation unless the cigarette is smoked to the very end. Experiments made (by Prof. Dixon) some years ago on boys showed that the Manilla cigar caused a considerable rise in blood pressure in five or six minutes, followed by collapse, representing respectively the stimulation and depression of nicotine on nerve-cells. No such effect could be obtained with cigarettes. The blood of cigarette inhalers, however, contains carbonic oxide, perhaps 5 per cent. for a man who smokes 20 cigarettes a day, and the vertigo, tremors, nausea, anæmia, and loss of memory for recent events are all symptoms which occur in chronic CO-poisoning. The cigar-smoker, on the contrary, absorbs a considerable amount of nicotine, and true nicotine poisoning may follow from excess.

"Some tolerance can be acquired to both nicotine and CO. Nicotine tolerance is brought about by destruction of the alkaloid in the body of the addict; since the alkaloid reaches the circulation slowly and in minute quantities the tissues are able to deal with it. CO-tolerance is known in animals, and is due to an increase in the number of red blood-cells and percentage of hæmoglobin."

Prof. Dixon attributed the pleasure of smoking partly to the stimulating and later narcotic properties of nicotine, though there are other factors like rhythm and sight to consider. Sir Arthur Pearson's experience regarding smoking by the blind (see p. 1088) has some bearing on this point. The influence of habit is rarely very strong, as most of the nicotine is destroyed during combustion. A smoker seldom forms a very strong craving and can usually stop or modify his addiction by the exercise of some little self-control; but were he to inject his nicotine the tale might be different.

POST-GRADUATE ACTIVITY IN LONDON.

THE Fellowship of Medicine and Post-Graduate Medical Association, with the coöperation of various special hospitals, is arranging to hold a series of special courses in general and special subjects during the forthcoming year, and the first of these, a six weeks' post-graduate course in General Medicine, will be held from Jan. 9th to Feb. 18th, 1922. The course will consist of a morning and an afternoon session, and the ground covered will include Pulmonary Affections, Heart Disease, Disease of the Nervous System, Fevers, Lunacy, &c., and the programme will be so arranged as to entail a minimum amount of travelling each day. The numbers attending the course will be limited, and early application for further particulars as to syllabus, fees, &c., should be made to the Secretary to the Fellowship, 1, Wimpole-street, W. 1.

OWING to pressure of space we have been compelled to hold over our Parliamentary Report till next week.

Dr. Gustave Monod will lecture on Syphilis of the Stomach at the Royal Society of Medicine on Wednesday, Nov. 23rd, at 5 P.M. Specimens will be shown, and it is hoped that the following, among others, will take part in the discussion: Dr. A. F. Hurst, Dr. J. W. McNee, Mr. Herbert Paterson, and Mr. A. J. Walton.

ACCORDING to statistical returns, which have been at the disposal of the Lettish Information Bureau (24, Gledhow-gardens, London, S.W.), there are 614 doctors in Latvia—that is, one doctor to every 2813 inhabitants. The following table will show how Latvia is situated in comparison with other countries.

Lithuania	180 doctors	i.e., one doctor to every	10,000 people.
Esthonia	382 "		3,077 "
Finland	1185 "		2,814 "
Sweden	—		3,656 "
Poland	—		5,750 "
England	—		1,000 "

LITERARY INTELLIGENCE.—Messrs. Baillière, Tindall and Cox announce the publication of the following books by Mr. G. Mayall, M.R.C.V.S.: Sheep and Goats; Cows, Cowhouses, and Milk (second edition); and Pigs, Pigstics, and Pork (second edition).

INFANT MORTALITY IN ABERDEEN.—At the distribution of attendance certificates in the Castlegate Mother and Child Welfare Centre on Oct. 31st, Dr. J. A. Stephen, the city M.O. for mother and child welfare, gave some important statistics regarding infantile mortality in Aberdeen. During the year 1920 there occurred in Aberdeen 170 stillbirths and many premature births, 133 children so born dying soon after birth; while of the 611 children who died before reaching the age of 1 year, about 120, or one-fifth, died during the first week of life. In addition, 38 mothers lost their lives within the first month after confinement. A large proportion of these deaths was preventable, and he appealed to the married women of Aberdeen to take the opportunity of learning what every woman ought to know. Dr. Matthew Hay said that in Aberdeen t were between 1200 and 1300 marriages every year, an women could easily attend the lectures. This y 200 women were attending the courses.

Correspondence.

"Audi alteram partem."

GENERALIA ON THE LOUSE PROBLEM ON THE WESTERN FRONT.

To the Editor of THE LANCET.

SIR,—I trust you will allow me, even at this late date, an opportunity of apologising to you and Dr. M. Coplans for an apparent lack of courtesy in not replying to Dr. Coplans's letter in your issue of April 30th. After my article of March 26th I watched for comment, but by mischance never saw the issue of April 30th and not till a short time ago was my attention called to it. I therefore take the earliest opportunity of sending this rejoinder.

I regret that the renewal of my acquaintance with Dr. Coplans begins in an atmosphere of misunderstanding—hardly controversy—as my former association with him in France was so pleasant, and I trust this letter will clear the air a little. Firstly, I fear I must hold to my own opinion as to the relative value of my manner of collecting data on lousiness compared with the official method cited by Dr. Coplans. I can conceive of no better way than mine—i.e., by doing the job personally and thoroughly from the front line backwards; living it, not reading it. Certain of my previous writings on the louse problem had such a curious war history that Dr. Coplans may be unaware of their existence, and perhaps I ought to have made it plainer that my "Generalia" should be read as complementary to them. Dr. Coplans will find that I dealt with many of his points in these writings, which concern the results of disinfestation work in England during June to September, 1917, after I had been recalled home for a commission from the Second Army, of which Dr. Coplans was D.A.D.M.S.(San.). The results of this work, carried on in collaboration with Captain J. T. Grant, R.A.M.C., and Mr. Bacot, which involved experiments with hot-air disinfestors—both of my own design and those of others—steam disinfestors, and the Clayton apparatus, were forwarded to the War Office in the form of reports. These, as well as those of others, with our consent were placed by the War Office in the hands of Prof. Nuttall, who was, and is, monographing the louse, in order to complete his presentation of "Combating Lousiness among Soldiers and Civilians,"[1] and also to secure their early publication and distribution. In this publication the reports are summarised or quoted and Prof. Nuttall makes all due acknowledgments. Here Dr. Coplans will find the detailed data on the relative capacities, &c., of various disinfestors upon which I base my individual judgment of their relative values. Here, also, are summarised the reports of Captain Gair, R.A.M.C., and Mr. Bacot, and that of Captain Grant, Mr. Bacot, and myself on the Clayton apparatus. He will also see that my work was essentially of a practical wholesale nature, carried on under service conditions, and this being so, I take strong exception to his inapposite remark "experimental work on disinfestation carried out under laboratory conditions may be highly successful given certain desiderata . . . ."

For reasons which I shall presently discover I confess to having deliberately ignored the Clayton apparatus in my article. It would have been better for me to have dismissed it with a few words. Dr. Coplans's opinion, "no type of disinfestor approaches the efficiency of the Clayton machine in dealing with verminous dwellings and their contents in situ," is like "the flowers that bloom in the spring" because I look at the question of the *disinfestation of lousy soldiers during a campaign*. If reference be made to "Combating lousiness, &c.," it will be noted that our experiments prove conclusively (to my mind) that in expense and general efficiency it is not to be placed, as a louse disinfestor under campaigning conditions, in the same category as the other types I mention in my article; I know that I am not alone in this opinion. I am open to correction, but I believe that the Clayton plants were bought before convincing tests showed their serious limitations in the field. Anyone who has personally wrestled wholeheartedly with the plant as an expert mechanic and I did on many a day, will understand why, far from having "no interest in the Clayton apparatus except its utility" (Dr. Coplans), I have, in fact, rather less. To prevent misunderstanding I express no opinion of the value of the plant as a house and ship disinfestor.

Concerning my report in the winter of 1916–17 on hot-air disinfestation, which Dr. Coplans quotes, it should be explained that my experiments never got beyond the preliminary; I was only beginning to discover the underlying principles. The work was then interrupted by my being detailed for experimental work at the new Laiterie disinfestor at Poperinghe. This was succeeded by six weeks' trench fever in hospital and then by experimentation with chemically impregnated clothing at the request of the War Office. About this same winter Captain R. Orr, C.A.M.C., in England, had been able to solve much of the problem.[1] I admit my judgment of 1916–17 was somewhat premature on certain points, but the seriously impairing effect of wet and muddy garments upon hot-air disinfestors still remains a fact. The modification of my views I owe largely to the work of Captain Orr.

I am afraid I cannot deal with certain passages of Dr. Coplans's letter, except by the following somewhat long personal statement.

Entomological Work during the War.

As a N.C.O.

1.	July – Sept., 1915	Work and lectures on flies and mosquitoes.
2.	Sept., 1915–Feb., 1916	Initial research on louse problem.
3.	Mar.–Sept. ..	Work on disinfestors and divisional bath routine.
4.	Oct.–Nov. ..	Investigation as to possible connexion of louse with Weil's disease; study of louse mouth-parts.
5.	Dec., 1916 – Mar., 1917	Initial work on hot-air disinfestation; lectures at Second Army school of sanitation for officers; work at Laiterie disinfestor; six weeks trench fever; experiments with impregnated clothing at War Office request (party and I segregated).

As an Officer.

6.	May–Sept. ..	Experiments in England on disinfestation methods.
7.	Oct.–Dec. ..	Trench fever work in England.
8.	Jan.–July, 1918	Attached to American Red Cross Trench Fever Commission in France.
9.	July–Sept. ..	Investigation of anopheline conditions in Flanders.
10.	Oct., 1918 – Mar., 1919	Attached No. 20 Gen. Hosp. for trench fever work.

I cite this in order to prove what little time I really had for instructional work or, to quote Dr. Coplans, "a free hand to conduct the necessary propaganda both at organised schools and elsewhere." I feel sure that Dr. Coplans will be surprised at this résumé. The most useful period of instructional work by lecturing was during the régime of Dr. Coplans when, as D.A.D.M.S. (San.), he gave me the best opportunity I ever had—that of meeting the medical officers of the Second Army. At other times my instructional work consisted mainly of interviews with all ranks interested in the business of disinfestation and in lectures given voluntarily and unofficially to such as cared to listen. Space does not permit me to make more than passing reference to all the provoking and unnecessary interruptions to which my work was subjected. I do not include in this the misfortunes due to campaigning. At the same time I acknowledge gladly the many facilities I did have granted and recall with pleasure the sympathy of the many charming fellows of all ranks whom I met. My "grouse," which is tempered by the cheerful fact that I was on the side that did win the war, is against a system. This by way of showing that I am not lacking in a sense of proportion. My experiences were only those of many a scientist

---

[1] Parasitology, vol. x.

The deaths from pulmonary tuberculosis within three months of notification were 357.

4. A special inquiry into 163 consecutive deaths not notified under the Regulations has shown: (*a*) That a large proportion (58) occurred in public institutions; (*b*) that many of the non-pulmonary cases were those of meningitis or specially complicated cases; (*c*) that in the 45 pulmonary cases, 22 (practically half) were not notified owing to a misunderstanding of the Tuberculosis Regulations, or to a belief that the case had already been notified. The Regulations direct in Article V. that a practitioner "shall not notify a case . . . if he has reasonable grounds for believing that the case has already been notified . . . to the medical officer of health for the district within which the place of residence of the person is situate"; and with the continuance of this clause—which at the most presents a rather unsatisfactory qualification as to notification—misunderstandings are almost certain to arise. No doubt the clause was inserted in an endeavour to avoid duplicate notifications in the same sanitary district, but in view of the liability of error, it would appear much more satisfactory to eliminate the qualification quoted above from the Regulations.

MEDICINE AND THE LAW.

The Definition of Live Birth.

AT the opening meeting of the Sheffield Medico-Chirurgical Society on Oct. 13th Dr. Godfrey Carter delivered the presidential address, taking as his subject an analysis of his last 100 post-mortem examinations. One of the topics dealt with in the address was the definition of live birth as laid down in courts of law when a mother is tried for the murder of her newly-born child. The point criticised was the necessity of proof that every portion of the child had been extruded when the act causing the death was performed, independently of whether breathing, movements, or other sign of life had occurred. The opinion of those present was that the birth should be treated as a live birth where, in other respects than that of complete delivery, the live birth of a full-term child has taken place, and where there is only evidence of an act of violence to which death can be attributed. A suggestion was made that an Act of Parliament should provide that "a child delivered at full-term and found upon medical examination to be healthy and free from any ascertainable cause of natural death, should be deemed to have been born alive, failing proof to the contrary." This, of course, would take part of the onus of proof from any prosecution for murder, and would lay it upon the accused person, and in other respects could not be carried out by the authority of any judge or judges. The principle of making the prosecution prove the case against the prisoner is too firmly established in our criminal law for it to be likely that Parliament would sanction departure from it in such a case. Apart from this, however, the test of complete extrusion from the mother might be considered and dealt with. If this test were abolished, and the result advocated by the Sheffield Medico-Chirurgical Society were attained, it would follow that many women and girls who are now convicted of concealment of birth would be convicted of murder or manslaughter. This, in short, is what was desired at the meeting referred to. To medical men who have examined the bodies of infants killed in the usual circumstances of such cases, it is clear, as a rule, when one of those felonies has been committed. It equally appears to them that such destruction of life ought to be punished severely and that punishment might check a certain wastage of human life, a result desirable in the interest of the nation. On the other hand, a verdict of murder entails the passing of the death sentence, and it is undesirable that this should be otherwise. A death sentence, however, in the case of nine out of ten of the mothers whose case is under consideration would never be carried out and would be a futile formality. A verdict of manslaughter would impose almost necessarily on the judge the obligation to pass a severe sentence. Either of these verdicts and their consequences would be contrary to public feeling, and would tend to rouse even more sympathy for the criminal than is now exhibited, whenever such trials take place. Moreover, the jury must find a prisoner guilty before sentence is passed, and modern experience agrees with that of bygone generations that where the sentence entailed is heavier than public opinion approves, juries refuse to convict. In these circumstances, whatever may be the strictly logical inference to be drawn from the conditions provable by medical men in the cases referred to it, it appears unlikely that the law will be altered, or that if altered, very different verdicts from those "merciful verdicts" now returned would ensue. The points suggested should always be weighed in connexion with this subject.

Action for Damages against a Medical Man.

A case of considerable importance to general practitioners has just been decided at the Suffolk County Assizes, where a patient brought an action for negligence against Dr. H. G. Wood-Hill, a well-known medical man of Beccles, and obtained heavy damages. The patient, while driving a dog-cart was thrown out and sustained an injury to her right leg. Dr. Wood-Hill was sent for and diagnosed a fracture of the upper third of the femur. He treated her by a Thomas splint and extension, and had her removed to the Beccles Hospital, where she was also examined by his partner, Dr. G. R. Fox, who agreed both as to the diagnosis and treatment, and did not consider that an anæsthetic was advisable. No radiograph was taken, and it came out that the X ray apparatus at the Beccles Hospital was out of order. The splint was removed and the weight taken away about five weeks after the accident, and Dr. Wood-Hill stated that he then found union to have taken place with only half an inch of shortening. He warned the patient against putting any weight on the leg for some time, and allowed her to go home to Hertfordshire about a fortnight later. Ten days after her return home she suddenly felt her leg give way. Dr. Cooper, her family doctor, was called in and he stated in his evidence that he found the right leg one and three-quarter inches shorter than the other, with pain, swelling of the buttock, and inability to raise the leg. He diagnosed the fracture to be in the neck of the femur, and advised an X ray examination, which confirmed his opinion. The patient was subsequently removed to the Freemasons' Hospital in London, where an operation was performed.

There was a marked divergence of opinion among the surgeons examined. While Dr. Cooper stated that the fracture was in the neck of the femur, and gave it as his opinion that an anæsthetic should have been employed at first, Sir Hamilton Ballance said that he thought an anæsthetic was not indicated, as any struggling would have increased the damage round the fracture. He believed that a re-fracture of the bone had occurred, owing to the patient putting too much weight on it, and expressed himself as satisfied with Dr. Wood-Hill's treatment. Mr. Hugh Ernest Griffiths and Mr. Harold William Wilson, assistant surgeons at St. Bartholomew's Hospital, confirmed Sir Hamilton Ballance's opinion.

The verdict of the jury was largely influenced by Dr. Wood-Hill's omission to have an X ray photograph taken of the injury, and the lesson of the case is that in such positions this aid to diagnosis should not be omitted.

UNIVERSITY OF MANCHESTER.—Mr. Stanley Wyatt, M.Sc., investigator to the Industrial Fatigue Research Board, has been appointed Special Lecturer in Psychology; Dr. D. E. Core, Lecturer in Neurology; Dr. A. E. Barclay, Lecturer in Radiology; and Mr. H. H. Rayner, Lecturer in the Surgical Diseases of Children. The following awards have been made: Leech Fellowships in Medicine, Dr. F. R. Ferguson and Dr. Eugenia R. A. Cooper. Graduate Scholarship in Medicine, Dr. G. V. Ashcroft; Tom Jones Memorial Surgical Scholarship, A. H. Southam.

immediately washed out with several quarts of hot water and solution of potassium permanganate, and more hot water, until the fluid returned clear. A wedge and gag were required to open the mouth. A pint of strong hot coffee was left in the stomach, and 0·50 caffein (Maison Clin ampoules) was injected intramuscularly. This caused a distinct improvement. I next saw him at 11 P.M., with Dr. Carruthers, who injected strychnine gr. 1/20. The boy's condition was then very grave—respirations 4 per minute, shallow and rattling; lips and ears deeply cyanotic, face pale. Pulse 124, running in type.

All the usual methods of reflex stimulation of the respiratory centre having been tried and failed, artificial respiration was started and oxygen administered—with the collaboration of Mr. E. W. Gandy—under pressure in a Clover's inhaler, for periods of a quarter of an hour, until 2 A.M. on the 25th. The effect of the oxygen was remarkable; the capillary venous stasis and cyanosis immediately disappeared, and the pulse improved in tone and rate (from 120 to under 100) at the end of each 15 minutes administration. At 2 A.M. he vomited lumps of undigested meat and vegetables, but no fluid, and by 5 A.M. he had recovered sufficiently under the standard methods of treatment to go for a walk in the garden. No after-effects were observed.

Afterwards, the boy stated that as he was troubled with insomnia—due probably to overwork and worry over some approaching examinations—he had taken the contents (half an ounce) of a bottle of morphia and atropine solution containing 24 gr. of morphia sulphate and 2 gr. of atropine sulphate to the ounce, which he had found in his father's surgery. There was no suggestion of suicidal intent. This was at about 4.15 P.M., some two and a half hours after a heavy mid-day dinner. The stomach washings revealed on analysis 1 gr. of morphia, but no atropine.

I am, Sir, yours faithfully,

J. G. WILLMORE.

Ministry of Pensions Hospital, Orpington, Nov. 12th, 1921.

THE STATUS OF MEDICAL EDUCATION.

To the Editor of THE LANCET.

SIR,—The whole medical profession owes a debt of gratitude to Sir Clifford Allbutt and others who, like him, are earnestly striving to improve the status of medical education in this country. One of the crying needs of the day in our profession is the breaking down of the artificially-created barriers between anatomy, physiology, medicine, and surgery. Fortunately, the type is now rare of professor or lecturer in anatomy or physiology who shuts himself up in his department, wilfully closing his eyes to the fact that his students will be the practitioners of the future, carefully avoiding any reference to the practical importance of the subject he lectures upon, and rarely associating in joint researches with his hospital colleagues. There is still, however, much room for improvement. It is surely a very extraordinary thing that with the example of John Hunter's life and work to point the way, so many of us close our minds to the rich harvest of knowledge which must accrue from the intimate coöperation of all branches of science.

May I be allowed to give an example of the unhappy state of affairs that results from this divorce that has been brought of late very forcibly to my notice. In the course of my researches into joint problems under the ægis of the Medical Research Council and with the kind help and collaboration of Prof. Shattock, I have been astonished at the prevailing lack of accurate knowledge of even the most elementary problems of the anatomy and physiology of the joints; the latter, in particular, may be regarded as a practically unopened book. Take the articular cartilages—our knowledge of their structure and nutrition and of their mode of repair cannot yet be said to be placed upon a firmly established basis. Again, what are the functions and essential microscopic structure of the synovial membranes? No two observers agree upon this point. Do they contain lymphatics and nerves? What is the composition of normal synovial fluid? I am unable to satisfy myself that anyone has ever analysed it, although fluids from pathological joints have been analysed by various observers. What is the effect of rest and movement upon the secretion of synovial fluid? Many other still unsolved problems might be quoted. Joint affections are extremely common in the community, yet we cannot hope to treat them rationally unless our treatment is based upon a sound knowledge of physiology and anatomy. Turning next to the large variety of conditions grouped together under the name "arthritis deformans" or "rheumatoid arthritis," we find that everything, including nomenclature, pathology, diagnosis, and treatment, is in a condition of chaos. There is a loss of public confidence in the profession in this matter which is, unfortunately, quite justified; many of the thinking and more highly educated members of the public are amazed that we are neglectful of these vital problems, and that we should rest content with an almost mediæval superstition and ignorance when in the realms of physics and chemistry and other sciences such marvellous discoveries have been made. Of writing of books upon arthritis there is no end; but most of them consist very largely of theory, and the most significant fact about all of them is that they contain no word about the normal physiology or intrinsic anatomy of the joint. We often rail at the unprofessional bone-setter, forgetting that, as Sir Arthur Keith has pointed out, the most powerful weapon in his armamentarium is our own ignorance of anatomy and physiology.

What is the remedy for this state of affairs? First, there must be the active coöperation to which we have already alluded. Secondly, the teaching of anatomy and physiology should be profoundly modified. Sir Clifford Allbutt holds that the time given to these preliminary subjects should not be cut down or diminished; I believe that Sir Charters Symonds argues that anatomy and physiology should be pruned and unimportant details of no practical significance omitted, the actual time devoted to these subjects being also shortened. This argument Sir Clifford Allbutt calls "utilitarianism." This is neither the place nor time to enter into an argument upon the *pros* and *cons* of "utilitarianism," but my impression is that the word has something to do with usefulness or utility (surely nothing derogatory in that). Is there not room for a course to be set midway between the views of these two distinguished men? Surely anatomy and physiology should be taught not as pure sciences but as applied sciences. Why? Because the average student is not learning these subjects in order some day to occupy a professorial chair, but to make himself more efficient in the alleviation of human suffering. The argument in favour of preliminary subjects such as anatomy being taught as pure sciences seems to be that they act as a "peculiar discipline" and "develop close observation and accuracy in a unique manner." It might well be asked, "Is it fair, to the public and to the budding doctor himself, when there is so much to be learnt in a short period to devote so much time and labour to details which are of no practical use to him in his after career, if the mental training can be equally well given in a way that does not diminish his power as a scientific and thinking physician or surgeon, and at the same time makes him a better handicraftsman?

How can this object be achieved without cutting down the time given to preliminary subjects? First, at least one weekly demonstration in anatomy and one in physiology should be held in the wards or out-patient departments of the hospital. It is almost impossible to exaggerate the interest and enthusiasm this procedure would arouse in the student's mind. Let us imagine, for example, that the lymphatics of the breast had been a subject of demonstration in the anatomical department. Let the class next see and examine in the hospital a case of cancer of the breast with lymphatic gland involvement. Let each examine the tumour and note its size, shape, consistency, &c. The dry anatomical facts will be infused with life, and the mind admirably prepared for the more serious clinical work to follow. Who will deny that the student's powers of close observation and accuracy will thus be increased far more than injustices as between different hospitals in the distribution of the grants; and they trust, therefore, that the condition will not be pressed.

(2) That copies of this resolution should be forwarded to the Prime Minister, the Chancellor of the Exchequer, and the Minister of Health, and the Voluntary Hospitals Commission.

These resolutions having been seconded by Sir ARTHUR STANLEY and supported by Mr. HOPKINSON, were, after discussion, put and carried.

The meeting closed with the usual votes of thanks.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

CITY OF LEEDS.

Dr. J. J. Jervis tells us that the year has been one of progress in every direction, as the vital statistics and other records embodied in the report show. The population was estimated by the Registrar-General at 448,913 for death-rate and 449,410 for birth-rate. The most important figures were as follows: Birth-rate, 25·01; death-rate, 14·68; infant mortality rate, 110; death-rate from pulmonary tuberculosis, 1·23; and from other forms of tuberculosis, 0·33. The death-rate from diarrhœa and enteritis under two years per 1000 births was 12·47. The figure of 8·3 represents the death-rate for England and Wales, and the table given on p. 16 shows that Leeds does not come out well in comparison with the 10 large English cities. Dr. Jervis has much to say on the smoke problem, pointing out that respiratory diseases as a group (including phthisis and influenza) were responsible for 31·3 per cent. of the total deaths. He believes that "prevention can only be achieved by tackling the smoke nuisance resolutely and compelling manufacturers to adopt cleaner and more rational methods of extracting heat from coal fuel and at the same time by extending the system of central heating for domestic purposes." Dr. Jervis shows that infant mortality from respiratory diseases was highest in those wards in which the atmospheric pollution is most marked, and suggests that where plant life fails to exist, it is impossible for the delicate human organism to escape some damage. From the paragraphs on smoke inspection we gather that the limit adopted is three minutes of dense smoke in the hour, and that although in 544 cases this limit was exceeded there were no prosecutions. We trust that public opinion will support the health committee of Leeds if it acts on Dr. Jervis's advice and institutes a really vigorous campaign.

Dr. Jervis wants more hospital accommodation for pneumonia, and suggests that some of the beds in the Poor-law infirmaries should be used to supplement the deficiency of the general hospitals in this respect. The pooling of the hospital accommodation of the Poor-law and sanitary authorities for the general interests of the community would appear to be a possible solution of many problems now confronting medical officers of health. Dr. Jervis does not believe in the grading of milk; he contends that those who suffer most from the drinking of impure milk are the working classes, many of whom are finding it hard enough even now to purchase sufficient milk and could not afford the higher price demanded for graded milk. Dr. Jervis reports that the quality of cattle arriving in Leeds for slaughter has shown a marked improvement since control was removed. He would like to see the closing of the private slaughter-houses and the provision of adequate accommodation at the public abattoir.

Seven beds are reserved at the Maternity Hospital for mothers and babies in case of ophthalmia neonatorum. Of 141 cases of this disease notified, five made an imperfect recovery, eight died, two were still under treatment, and six were lost sight of owing to removal. The work done by the V.D. clinics has increased; 2607 new cases of syphilis and gonorrhœa attended, 820 patients discontinued treatment before being pronounced cured, of which a very large proportion were still capable of transmitting the disease to others. "There is urgent need," continues Dr. Jervis, "for Parliamentary powers to compel infected individuals to continue treatment until cure is effected." The death-rate from pulmonary tuberculosis in Leeds showed an increase during the war years and has now again reached pre-war levels. The Ministry of Health have withheld approval of a scheme for the dental treatment of the tuberculous on the score of expense, and the provision of a new sanatorium at Moortown with beds for 320 cases has been postponed for the same reason. The corporation have taken over the two tuberculosis hospitals (Armley House and Gateforth) belonging to the Voluntary Tuberculosis Association. There is a comprehensive scheme for maternity and child welfare. The ante-natal work is growing, but, as elsewhere, the reduction in infant mortality does not extend to the neo-natal mortality. The deaths from puerperal fever have risen from six in 1919 to 29 in 1920. Dr. Jervis emphasises the need for the establishment of small maternity homes in the congested working-class areas.

Dr. Jervis is strongly in favour of public health propaganda by sanitary authorities and says that in Leeds this policy has been adopted with the best results. The housing problem is rendered specially difficult in Leeds by the large number of back-to-back houses. Of the total 113,310 houses in the city, 34,904 are "through" houses and 78,406 are back-to-back. Dr. Jervis divides the back-to-back houses into three groups. The first or oldest group, numbering 35,100, built in long unbroken rows, "is frankly bad and unhealthy, and must be got rid of as soon as practicable." The second group, numbering 29,082, and built in blocks of eight, "is better, but requires drastic improvement to bring it up to standard." The third group, the erection of which was approved up to 1909, numbers 14,224, and "consists of a good type of house which, while not quite up to the standard of the modern through house, does not fall very far short of it." Apart from the question of the back-to-back houses, there is an estimated shortage of 5800 houses owing to house-building being in abeyance during the war. The progress of the housing schemes has been very slow—only 309 have been completed; but there are now some signs of speeding up and it is hoped about 1000 will be completed before the end of the current year. A strenuous effort is being made to overtake the arrears of sanitary work and repairs left by the war.

The Services.

ROYAL ARMY MEDICAL CORPS.

Lt. (temp. Capt.) E. H. W. Elkington to be Capt.

TERRITORIAL ARMY.

Lt.-Col. F. W. Gibbon, having attained the age limit, is retired and retains the rank of Lt.-Col., with permission to wear the prescribed uniform.

Maj. J. O. Summerhayes resigns his commn. and is granted the rank of Lt.-Col., with permission to wear the prescribed uniform.

Capt. J. J. E. Biggs to be Maj.

Capt. W. A. Jackman (late R.A.M.C., Spec. Res.) to be Capt.

1st N. Gen. Hosp.—Maj. D. W. Patterson, having attained the age limit, is retired, and is granted the rank of Lt.-Col.

TERRITORIAL ARMY RESERVE.

Lt.-Col. J. B. Jamieson, from General List, to be Lt.-Col.

Maj. M. A. Archdale, having attained the age limit, is retired and retains the rank of Maj.

WESTMINSTER HOSPITAL.—A dance in aid of this hospital and medical school will be held at King Edward VII. Rooms, Hotel Victoria, Northumberland-avenue, London, W.C., *on Friday, Dec. 2nd. Tickets (£1 1s.)* may be obtained from the hon. secs., Mr. A. D. Hepburn and Mr. J. Wilson, at the hospital.

Obituary.

SHERIDAN DELÉPINE, B.Sc. LAUSANNE, M.B., C.M. EDIN., M.Sc. MANCH.,

PROFESSOR OF PUBLIC HEALTH AND BACTERIOLOGY AND DIRECTOR OF THE PUBLIC HEALTH LABORATORY, UNIVERSITY OF MANCHESTER.

WE *much regret to announce the death of Prof.* Delépine, professor of public health and bacteriology in the University of Manchester, which occurred on Sunday last at his home in Withington.

Auguste Sheridan Delépine was 66 years of age at the time of his death. He was the son of a French father and a Swiss mother, and was educated in Paris, Geneva, and Lausanne, graduating in science at the last place with distinction, *and while still quite a boy.* Thence he proceeded to the University of Edinburgh, where he pursued medical studies, *and in* 1882 *graduated* as M.B., C.M. with first-class honours. He was interested from the first in pathological anatomy and in the developments of the then new science of bacteriology, and after *acting at Edinburgh* as demonstrator in these subjects, came to London and shortly afterwards was appointed demonstrator of pathology and curator to the museum at St. George's Hospital. The St. George's Hospital *medical school* was at that time a large one, and Delépine did excellent work both in assistance to the clinical routine of the hospital and in the instruction of a long series of pupils, many of whom had ample *reason* later to be grateful for his painstaking and lucid demonstrations.

Some eight years later—namely, in 1891—*he* proceeded to Manchester, where he was appointed the first Procter professor of pathology and morbid anatomy. All the arrangements for a new pathological department at Manchester, with a bacteriological laboratory in attachment, were carried out under Delépine's instructions, and when later the connexion between the University Medical School and the Royal Infirmary became the close one that it now is, Delépine, as professor of pathology in the University, became official pathologist to the institution. Our columns and those of the scientific press generally have borne frequent witness to the good work that he did there, and that was done under his ægis by assistants and pupils. His investigations, for example, into the source of tubercle bacilli in cows' milk, into the bearing of the outbreaks of food poisons upon the ætiology of summer diarrhœa, and into the general conditions necessary to obtain a clean milk-supply, form good examples of thoroughly scientific work directed towards practical ends. At the same time Delépine was the originator of two mechanical appliances valuable in physical and bacteriological technique—namely, a gas-sphygmoscope and a convenient modification of the microtome.

After 20 years as professor of pathology, during which time great practical assistance was afforded to the sanitary authorities of Manchester and Salford by the scientific researches carried on in the laboratory, a public health department was instituted in the University of Manchester, and Delépine, having resigned the *chair of* pathology, was appointed professor of public health and bacteriology and director of the public health laboratory. From this laboratory an admirable series of researches emerged connected with the immediate sanitary needs of Manchester, Salford, and the surrounding districts. At the laboratory Prof. Delépine *gave instruction* to a large number of graduates intending to take the diploma in public health of the University, and while some of these assisted in conducting research work, others were employed in maintaining the public health of the locality by making careful reports upon the incidence and spread of preventable disease. No more sound course in practical hygiene was given at any medical school than at Manchester under Delépine.

During the war Delépine did good work in an advisory capacity as sanitarian and bacteriologist, and in particular his researches were found extremely pertinent in the treatment of trench foot. A brief article on frost-bite, published in THE LANCET in February, 1915, at the close of the first winter of war, pointed the way to the prevention of a condition that was costing the allied armies many lives, as well as causing enormous inefficiency, pain, and crippling.

Delépine had been in delicate health for some time, and there seems no doubt that his life was shortened by the tragedy that overtook him when he lost his only son in the war. By his friends he will be remembered warmly for his geniality and courtesy, and by all who came into relations with him for his simplicity and firmness.

SIR GEORGE JOSEPH HAMILTON EVATT, K.C.B.,

MAJOR-GENERAL A.M.S. (RETD.).

Major-General Evatt who, *during his life, played* a prominent part in the reform of the medical and nursing services of the army, *died in London on* Nov. 5th. We have briefly chronicled the event. He was within *a few days of his seventy-ninth* year at the time of his death.

The son of Captain G. Evatt, he was *educated at the* Royal College of Surgeons in Ireland, won a gold medal at Trinity College, Dublin, and qualified in 1863 as L.R.C.S.I., and M.D.R.U.I. Three years later he entered the Army Medical Service, *being attached* to the 25th King's Own Scottish Borderers. He first saw service with the Perak Expedition with Sir H. Ross's Bengal column in 1876, for which he obtained the medal and clasp; *he was promoted to* Surgeon-Major in the following year. In the Afghan War of 1878-80 he was at the *capture* of *Ali Masjid* and was mentioned in despatches, as he was also in the advance on Gundermak, *and in the return in the* "Death March" of 1879, when he was specially thanked in General Orders by the Viceroy *in Council and by* the Commander-in-Chief in India. He also commanded a field hospital in the second campaign which included the advance to Cabul under General Sir Charles Gough, the action on the Ghuzni Road, and the return to India. In 1885 he became a Lieut.-Colonel in the R.A.M.C., in which year he served in the Suakin Expedition, including the actions of Handub, Tamai, and the removal of the *wounded from* MacNeill's zareba, being again mentioned in despatches and receiving for his services the *medal and clasp* and Khedive's Star. He was also in the Zhob Valley Expedition of 1890 and *commanded a field hospital,* when he again received mention in official records.

Evatt had now reached *the rank of Surgeon-General* and from 1880 to 1886 he held the post of medical officer to the Royal Military Academy, Woolwich; from 1887 to 1891 he was senior medical officer at the Quetta Garrison, Baluchistan; *from* 1892 *to* 1894 sanitary officer to the Woolwich Garrison; from 1894 to 1896 secretary of the Royal Victoria Hospital, Netley. He again served abroad and for three years was principal medical officer in China, *holding a* similar office in the Western District of England from 1899 to 1902, after which he became Surgeon-General to the Second Army Corps at Salisbury. In conjunction with Mr. (now Sir James) Cantlie, Evatt organised the Volunteer R.A.M.C. in 1883, and a few years later drew up a scheme for the Army Nursing Service Reserve. He also founded the Medical Officers of Schools Association. An indefatigable worker, he associated himself with many activities which had a bearing upon the health of the nation, and was a member of the committee of the International Health Exhibition of 1884, a vice-president of the British Medical Temperance Association, a member of the Council of the Royal Army Temperance Association, and President of the Poor Law Medical Officers Association. In 1886 he contested unsuccessfully Woolwich as a Liberal, in 1906 the Fareham Division of Hampshire, and in 1910 Brighton. During the war, 1915–16, he was *president* of the Travelling Medical Board, Western Command. He contributed largely in khaki who, if they were wise, cultivated in those strenuous times what all Tommies did—a sardonic philosophy and a sense of humour.

Touching the matter of responsibility for the conduct of a louse campaign, I should be sorry indeed if the rank and file of medical and sanitary officers thought I disparaged their feelings and efforts. Perhaps certain of your readers, erstwhile campaigners, may remember that I fought and taught that the regimental and front area medical officers had not the time and opportunity for disinfestation work on the necessary large scale. Neither is it hidden in my writings that such is even beyond an army D.A.D.M.S. (San.), subject as he is to all manner of official limitations. Even more than Dr. Coplans's assistance in those days I acknowledge his appreciation and understanding, but even he himself will admit how little realised, through no fault of one's own, may be the bright ideas of a D.A.D.M.S. So what chance for a louse campaign in the grand manner had a lance-sergeant. I must therefore emphatically decline to be saddled with any responsibility for the conduct of the strategy of the louse campaign. A field-marshal's baton is no good in a lance-sergeant's knapsack.

In conclusion, Dr. Coplans's quotation of Mr. Dan Jenkins, "The Labour Party desires for the working man and his family, at home, the same standard of medical organisation, skill, and care as was shown for the British armies in France, &c.," is somewhat loose. I take it to mean rather a testimony to the nationalisation of medical effort, because no soldier, let alone a member of the Labour Party in khaki, would ever subscribe to the idea that the problem of his war-time lousiness was ever tackled with complete success.

I am, Sir, yours faithfully,

A. D. PEACOCK.

Armstrong College, Newcastle-on-Tyne, Nov. 12th, 1921.

TRYPANOCIDE.

To the Editor of THE LANCET.

SIR,—In August last it fell to my lot as sectional editor of the *Tropical Diseases Bulletin* to write a critical review of recent work on sleeping sickness. For reasons which are clearly stated at the commencement of my review I decided to deal mainly with the work of Marshall and Vassallo. Judging from Dr. E. T. Jensen's letter, published in your issue of Nov. 12th, this review has caused considerable distress to him, and to a recently self-constituted body, the Tropical Diseases Prevention Association, of which he is the hon. secretary.

I may say at once that until I read an annotation in THE LANCET of Sept. 10th—the day on which my critique was forwarded to the Tropical Diseases Bureau for publication—I was ignorant of the fact that Dr. Jensen's Association was acting as sponsor to Marshall and Vassallo. My object in writing the review was simply to present to the readers of the *Bulletin* a critical analysis of the work on which Marshall and Vassallo based their sweeping claims; and as the result of a most careful consideration of their papers I reached the following conclusions:—

1. The work is based on two fundamental assumptions, both of which are incorrect, or at least can only be accepted with very considerable qualification.

2. The treatment is not new, even for trypanosomiasis, but is substantially the same as that tried by Reichenow in 1914, and abandoned by him as useless in that it failed to sterilise the cerebro-spinal fluid.

3. Marshall and Vassallo produce no satisfactory evidence that intrathecal injections of salvarsanised serum sterilise infected cerebro-spinal fluids.

4. The results, so far published, fail to substantiate the claim that the treatment gives better results than any hitherto obtained by other methods.

Scientifically Dr. Jensen's letter is of no value, as he does not attempt (probably because he is unable) to controvert the arguments on which I based these conclusions. He points out that the work done by Marshall and Vassallo was performed by them as Uganda medical officers, and in their spare time. This may account for the unsatisfactory nature of Marshall and Vassallo's observations, but it certainly does not invalidate my conclusions, nor is it likely to inspire belief in Marshall and Vassallo's claims, or respect for the judgment of Dr. Jensen and his Association.

Dr. Jensen, however, is mainly concerned in defending the position of the Tropical Diseases Prevention Association, and in view of the youth of this body it would, naturally, resent anything which might suggest that it had been guilty of a gross error of judgment. Even though willing to make full allowance for his sensitiveness on this point, I cannot refrain from pointing out to Dr. Jensen that he has descended to somewhat questionable tactics. In the first place, he states that I published my critical view "in a medium which precluded the possibility of a reply." This is an unpleasant suggestion, and in view of the publication of his lengthy letters in *The Lancet* and in the *British Medical Journal*, the complaint seems unjustifiable. I do not know whether he has communicated with the editor of the *Tropical Diseases Bulletin*, but although I can well believe that a letter of the kind in question might be refused publication, I do not believe that anything of scientific value would be rejected. In the second place, Dr. Jensen loudly protests that his Association "is not prejudiced in favour of any one method of treatment, but it does consider that fair play should be given to any method which has shown promise of success." Such platitudes may satisfy Dr. Jensen, and certainly they do nobody any harm, but it is rather amusing to read in the next line that one who has had the temerity to differ from the Association on a matter of the value of evidence is accused of lacking a sense of fair play. In fact there is a delicate insinuation that I have purposely belittled Marshall and Vassallo's work in order to promote the interests of a certain German chemical firm.

Dr. Jensen's letter closes with a remarkable homily, which runs as follows: "It is, perhaps, not fully recognised by tropical experts working at home that treatment of such a disease as sleeping sickness must be administratively and economically practicable on a large scale as well as scientifically effective in a hospital at home." Possibly this is the case, but how it touches the question at issue is obscure, unless it is intended to have a personal application. If so, I can only point out that it comes strangely from the pen of one who, so far as I am aware, has contributed nothing to our knowledge of the disease, and deplore the fact that one who is so little conversant with the literature of the subject should have attempted the task which Dr. Jensen has undertaken.

I am, Sir, yours faithfully,

WARRINGTON YORKE.

Liverpool School of Tropical Medicine, Nov. 14th, 1921.

BELLADONNA POISONING.

To the Editor of THE LANCET.

SIR,—In connexion with the case of belladonna poisoning reported in your last issue by Dr. H. Neville Taylor, the following may be deemed worthy of record. It illustrates (1) recovery after ingestion, by a schoolboy of 15, of 12 gr. of morphia, and 1 gr. of atropine in solution three hours previously; (2) the effect of delayed absorption due to food; (3) the response to remedial measures, especially oxygen under pressure, in an apparently hopeless case.

At 7.20 P.M. on July 24th, 1920, I first saw the patient in the absence of Dr. S. W. Carruthers, of Upper Norwood, who was his family physician. The boy had been found completely unconscious in a deck chair in the garden by his father, a veterinary surgeon; he could not be roused by any of the usual means. His condition was as follows: *Pupils widely dilated, not reacting to light*; conjunctival and corneal reflexes absent; temp. subnormal, P. 120, respiration stertorous (14 per minute); jaws clenched; knee-jerks increased; plantar reflexes brisk, extensor response; legs spastic, no head retraction or Kernig's sign; lips and ears cyanosed; face flushed, skin dry; lungs, a few rhonchi and bubbling râles; other organs, nothing noteworthy.

In the absence of any history of previous illness, or data bearing on the patient's condition, the stomach was

F. C. O. Valentine, Cambridge and London; G. T. Verry, St. Bart.'s; A. S. H. Walford, Cambridge and St. Thomas's; A. L. Walker, Cambridge and Middlesex; G. C. Wellish, Sydney and Middlesex; D. R. Wheeler, Belfast and Middlesex; J. G. Whitaker, Melbourne and Middlesex; P. B. Wilkinson, King's Coll.; V. Wilkinson, Cambridge and Middlesex; and A. L. Yates, St. Bart.'s.

University of Glasgow.—The following degrees were conferred on Nov. 12th:—

Doctors of Medicine (M.D.).

1. *With Honours.*—Douglas Kinchin Adams, M.A., B.Sc., M.B., Ch.B.; Thomas Jones Mackie, M.B., Ch.B.; Noah Morris, B.Sc., M.B., Ch.B.
2. *With High Commendation.*—William Taylor, M.B., Ch.B.
3. *With Commendation.*—Charles Cameron, M.A., M.B., Ch.B.; Ronald Thomson Grant, M.B., Ch.B.; Robert Cecil Robertson, M.B., Ch.B.; Herbert Watt Torrance, M.B., Ch.B.
4. *Ordinary Degree.*—John Broadfoot, M.B., Ch.B.; Ethel Crawford, M.B., Ch.B.; James Paterson Crawford, M.B., Ch.B.; Andrew Garvie, M.B., Ch.B.; William Hogarth Kerr, M.A., M.B., Ch.B.; Duncan Mackenzie MacRae, M.A., M.B., Ch.B.; George Taylor, M.A., M.B., Ch.B.

Bachelor of Medicine and Bachelor of Surgery (M.B., Ch.B.).

With Commendation.—Andrew Allan Bell.

Royal Faculty of Physicians and Surgeons of Glasgow.—At the annual meeting of Fellows, held on Nov. 7th, the following office-bearers were elected:—President: Dr. W. G. Dun; Visitor: Dr. W. R. Jack; Treasurer: Mr. George McIntyre; Hon. Librarian: Dr. E. H. L. Oliphant; Councillors: President, Visitor, Treasurer, Hon. Librarian (all ex officio), Dr. James A. Adams, as representative to the General Medical Council (ex officio), Mr. R. M. Buchanan, Dr. Ebenezer Duncan, Mr. Henry Rutherfurd, Dr. A. K. Chalmers, Sir Kennedy Dalziel, and Mr. J. Mason Noble.

Royal College of Physicians of Ireland.—At a meeting of the President and Fellows of the Royal College of Physicians of Ireland held on Nov. 4th, Dr. Robert Marshall, of Belfast, and Dr. Victor M. Synge, of Dublin, were sworn in as Fellows of the College, and Dr. Patrick Ley, of Dublin, was admitted a Member.

University of Sheffield.—The University Council has made the following appointments:—Dr. W. W. King to the post of Lecturer in Gynæcology, and Mr. G. H. Froggatt, L.D.S. Eng., to the post of Lecturer in Dental Mechanics.

London School of Tropical Medicine: Annual Dinner.—The annual gathering which took place at the Trocadero Restaurant on Nov. 9th was a good example of the *ola tuta*, which is the motto of the school. Prof. A. Alcock, who presided, made a learned survey of the achievements of tropical medicine and the share taken in them by the London School. Its two chief remaining needs—a chair of biochemistry and a department of tropical hygiene—he hoped would soon be met. Col. R. H. Elliot, in proposing the "Guests," paid admiring tribute to the rival school at Liverpool, and Col. J. J. Pratt's graceful speech did no more than justice to the chairman's own services in the region of medical entomology. The point was usefully brought out that the time has now gone past for expeditionary forces, the hope of the future lying rather in local centres, permanently staffed and equipped but still in close touch with a central school. The dinner was again noteworthy in the support that it received from the present students of the school, many of them drawn from distant parts of the world.

National Council for Combating Venereal Diseases.—At a meeting of the Council held at the House of the Royal Society of Medicine on Nov. 11th the following resolution was proposed by Mr. E. B. Turner, chairman of the Medical Committee, and seconded by Mr. Kenneth Walker, joint honorary medical secretary.

> That the Executive Committee be directed to appoint a Committee of Enquiry with instructions to prepare a full and detailed report on the working of ablution centres and that this report be laid before the Council at its next meeting.

The resolution was carried unanimously, as was the following rider, proposed by Miss Alison Neilans, of the Association for Moral and Social Hygiene, and seconded by Mr. Kent, of the Alliance of Honour:—

> The Committee so appointed shall include men and women representatives and shall take into consideration the social and moral effects as well as the medical results of providing and advertising the ablution centres.

A vigorous address was delivered by Lord Gorell, the President of the Council, protesting against the misrepresentations of the work of the Council in certain quarters.

Dr. A. J. Rice-Oxley, J.P., has been elected Mayor of the Royal Borough of Kensington for the third time.

National Hospital for the Paralysed and Epileptic.—A sum of over £500 was raised in connexion with the bazaar held on Founders' Day, Nov. 2nd.

Royal Sanitary Institute.—The next Congress is being arranged to be held at Bournemouth from July 24th to 29th, 1922.

Glasgow University Club, London.—The autumn dinner will be held in the Holborn Restaurant, London, on Friday, Nov. 25th, at 7.30 P.M., Prof. J. Millar Thomson, F.R.S., presiding.

19th C.C.S. Annual Dinner.—The third annual dinner will take place in London on Friday, Nov. 25th. Tickets and further particulars may be obtained from the Dinner Secretary, Rev. E. C. Doddrell, 6, Alexandra House, Regent's Park-road, Finchley, London, N. 3.

Middlesex Hospital Medical School.—An emeritus lecture will be delivered on Feb. 7th, 1922, at 3 P.M., by Sir John Bland-Sutton, the subject of the lecture being the Choroid Plexuses of the Brain and Psammoma.

University College Hospital Medical Society.—The annual dinner of the Society will be held at the Restaurant Frascati on Monday, Dec. 12th, at 7.15 for 7.30 P.M. Tickets, price 10*s.*, may be obtained from the hon. sec. or the resident medical officer at the hospital.

Medical Officers of Schools Association.—The annual general meeting of the Association will be held at 11, Chandos-street, London, W., on Tuesday, Nov. 29th, at 5 P.M., when the President, Mr. R. C. Elmslie, will deliver an address on the Status of Physical Instructors in Schools, to be followed by discussion.

Classes for Stammerers.—The Board of Education has decided that the classes for stammering children shall in future be regarded as "arrangements for attending to the health and physical condition of children educated in public elementary schools." This has enabled the London County Council, which is at present responsible for six such classes, to regard them as forming part of the school medical service.

Medical Women's Federation.—The Council of the Federation held its autumn meeting in Edinburgh on Nov. 11th and 12th. Twenty-two members, representing the ten different associations of the Federation in Great Britain, were present. A long discussion took place on the situation raised by the recent dismissal by the Glasgow Corporation of three married medical women, who for some years had been employed in its child welfare and tuberculosis departments. When appointed they were already married; now they were dismissed at the instance of the Labour members of the corporation, who object to the employment of all women whose husbands are earning a regular income. The recent dismissal of Dr. G. Miall-Smith by the St. Pancras Borough Council, on account of her marriage since her appointment, nothing precluding marriage having been inserted in the terms of her contract, also came under consideration. It was felt strongly by the Council that it is not the function of the State or of any public authority to inquire into the private and economic affairs of men or women who apply for medical appointments. It was agreed that persons should be allowed to hold office because of their individual capability to perform the assigned duties. If inquiries were uniformly pressed, it would mean the exclusion from public service of many men who by inheritance or marriage have sufficient money to maintain a small home. The following resolution was carried unanimously:—

> That this Council records its opinion that marriage should be no bar to the holding of posts by medical women, and considers their exclusion is entirely contrary to the spirit of the Sex Disqualification (Removal) Act, 1919, and against public policy.

The need for maintaining the standard advocated by the British Medical Association of equal pay for equal work in the case of medical men and women was once more emphasised by the Council, in view of the danger of women being invited by public health authorities to accept a lower salary than is deemed essential for men. The Council considered that the infringement of this principle would be to the detriment of the profession as a whole, and is doing everything in its power to discountenance "underselling" on the part of medical women. Amongst other subjects raised, that of birth control was prominent. A subcommittee was appointed to study the subject from all points of view, in order to ascertain the ultimate effects of birth control upon imperial health and welfare. Attention was drawn to the desirability, already recognised by many superintendents, of the employment of medical women in large mental hospitals in the interests of women patients.

if, for example, he had carefully dissected the relationships and connexions of the otic ganglion or the origin and insertion of the various individual elements of the erector spinæ muscle. There will, of course, be minor difficulties to be overcome—such as, for example, those connected with the arrangement and selection of the clinical cases—arrangements would be necessary between the demonstrators of anatomy, physiology, and the surgical and medical registrars—a most welcome and healthy fusion of ideas and research work would follow almost as a matter of course. The second manner in which this object may be achieved lies with the teacher of anatomy and physiology himself. It is desirable, if possible, that the teacher of anatomy should hold the Fellowship of the College of Surgeons or other high surgical degree or diploma, and should conscientiously keep himself in touch with modern advances in surgery and pathology. In the same way it is eminently desirable (and this fortunately is often the case) that the teacher of physiology should have distinguished himself in medicine, and should likewise have kept in touch with the progress of medicine.

How few there are who wander round the Hunterian collection at the Royal College of Surgeons—the admiration of the scientific world—who grasp the real message of its serried ranks of silent yet eloquent preparations. John Hunter—his body tortured with suffering, his mind burdened with the cares of one of the largest private practices in London—gave his fortune and every moment of his spare time to the formation of this magnificent collection, because his genius knew that the appeal to the eye is greater than written or spoken word. There is a crying need at the present time for us in our researches humbly to follow in Hunter's footsteps, and to break down the absurd barriers built by narrow-mindedness between the divisions of a science which in reality is one and undivisible.

I am, Sir, yours faithfully,
A. G. TIMBRELL FISHER,
Hunterian Professor of the Royal College of Surgeons of England, 1920–21, 1921–22, &c.
Harley-street, W., Nov. 7th, 1921.

ADENOIDS AND RICKETS.

To the Editor of THE LANCET.

SIR,—In his article in your last issue on the essential causes of adenoids and their association with rickets, Dr. H. Merrall hardly does justice to my exposition of the causation of adenoids in stating that "Cautley, whilst attaching some importance to the vicious circle of adenoids and catarrh, believes bottle-feeding and rickets mostly to blame." It is true that I ascribed to rickets many of the ill-effects which are thought due to adenoids, and that I pointed out the increased frequency of adenoids and rickets since the introduction of bottle-feeding. But I summed up by saying that the prevention of adenoids is mainly concerned with the prevention of rickets and nasal catarrh, guarding the child against exposure to infection, and treating nasal catarrh seriously; and that if you guard a child against infection you will probably guard it against hyperplasia of the adenoid tissue.

Obviously I agree with Dr. Merrall that frequently recurring colds are the chief cause, but I regard rickets as an important concomitant factor, inasmuch as catarrh of the mucous membrane is the most common early sign of this disease. Throughout my introductory remarks the importance of nasal catarrh was strongly emphasised, rickets being regarded as a cause of catarrh. The association of adenoids and deformity of the jaws was insisted on, but did not receive much attention in the subsequent discussion. Almost all children with adenoids are rachitic. Probably the deformity is the result of the association of nasal obstruction with rickets rather than due to either cause acting independently.

I am, Sir, yours faithfully,
Park-street, W., Nov. 12th, 1921. EDMUND CAUTLEY.

THE ÆTIOLOGY OF ADENOIDS.

To the Editor of THE LANCET.

SIR,—In view of the alarming prevalence of "adenoids" in this country it is greatly to be regretted that the pathology of this disease has not yet been definitely settled. In his paper on the subject, published in THE LANCET of Nov. 12th, Dr. H. Merrall emphasises the part played by oft-repeated colds in the ætiology of adenoids. Doubtless he is right here. But this is not the beginning of the story. Why these oft-recurring colds? Are they not the result of the *status catarrhalis*, so ably described by Dr. H. C. Cameron, a condition which is, in large measure at least, the result of improper food? Unfortunately in a large proportion of the medical problems which confront us the data at our disposal do not admit of a logical conclusion; we have to be content with hypotheses: but I venture to suggest that, as regards the ætiology of adenoids, a logical conclusion *can* be arrived at. Thus:—

Adenoid disease is more common among the British than among any other people. Wherever the British settle, be it in Australia, New Zealand, South Africa, or Canada, there adenoid disease is rampant among the British children. This cannot be because the British are hereditarily more liable to adenoid disease than other peoples, since there is evidence that the British of not many generations back did not greatly suffer from this disease. The one material environmental factor common to the British settlers in various parts of the world, but not shared by other peoples, is the food: the British take their dietetic customs with them wherever they go.

Ergo, a cause of adenoids is to be sought for in the nature of the British dietary.

If there is a flaw in this argument I should be glad to have it pointed out.

Cease to feed children on an excess of sugar and soft starchy foods and I venture to predict a pronounced diminution in the present disastrous prevalence of adenoids among us.

I am Sir, yours faithfully,
HARRY CAMPBELL.
Wimpole-street, W., Nov. 12th, 1921.

THE STAFF OF HOLLOWAY HOSPITAL.

To the Editor of THE LANCET.

SIR,—It will interest your readers to hear that the Voluntary Nursing Advisory Board for Holloway Gaol went to the Prison Commissioners' Office on Monday, Nov. 7th, and were most kindly received.

After considerable discussion, the following points were agreed on:—The Holloway Hospital is to be staffed entirely by certificated nurses, reasonable time being allowed for the absorption of the existing officers where not certificated. In this way it is hoped that all difficulties may be overcome, and that the matron, with the assistance of a trained and certificated staff, may be in a position to secure the good nursing of the patients confided to her care. The Voluntary Nursing Advisory Board expressed their appreciation of the good services rendered by the unqualified officers who have prison training only, and announced their intention of sending a special message of thanks to one of these, who is likely to be taking up work elsewhere.

I am, Sir, yours faithfully,
MARY SCHARLIEB.
Harley-street, W., Nov. 12th, 1921.

DONATIONS AND BEQUESTS.—The late Mr. John Ward Cousins left property of the gross value of £14,138, of which £12,278 is net personalty. Subject to certain life interests the testator gives, among other bequests, £3000 each to the Portsmouth, Portsea, and Gosport Hospitals; £300 to the Portsmouth and South Hants Eye and Ear Hospital; and £200 each to Dr. Barnardo's Homes, the Shaftesbury Society and Ragged School Union, and the Young Men's Christian Association.

FRIDAY.—12.15 P.M., Dr. Burnford: Applied Pathology. 2 P.M., Mr. Sinclair: Surgical Out-patients. Dr. Pernet: Skin Department. Mr. Banks Davis: Diseases of the Throat, Nose and Ear. 5 P.M., Mr. Steadman: The Ætiology and Pathology of Dental Sepsis (Lecture).

SATURDAY.—10 A.M., Dr. Arthur Saunders: Medical Diseases of Children. Dr. Burnford: Visit to Medical Wards. 2 P.M., Dr. Owen: Medical Out-patients. Mr. Simmonds: Surgical Out-patients.

Daily:—10 A.M., Visit of Post-Graduates to Wards. 2 P.M., In-patient, Out-patient Clinics and Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Nov. 21st.—10 A.M., Mr. W. E. Tanner: Surgical Out-patients. 2.30 P.M., Dr. A. J. Whiting: Demonstration in Medical Wards. Mr. E. Gillespie: Surgical Operations. Dr. J. B. Alexander: Medical Out-patients. Mr. J. Bright Banister: Gynæcological Out-patients. Dr. Shanks: X Ray Department. 4.30 P.M., Mr. J. Bright Banister: The Relation of Heart Disease to Pregnancy, Labour, and the Puerperium. 7 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.

TUESDAY.—9.45 A.M., Lt.-Col. R. H. Elliot: Eye Cases and Operations. 2 P.M., Mr. J. Howell Evans: Surgical Out-patients. 2.30 P.M., Mr. H. W. Carson: Surgical Operations. Mr. C. H. Hayton: Throat, Nose and Ear Out-patients. Dr. J. Metcalfe: X Ray Department. Dr. L. Yealland: Medical In-patients. 3 P.M., Mr. J. Howell Evans: Surgical In-patients. 3.30 P.M., Dr. F. G. Crookshank: Physical Examination of the Chest.

WEDNESDAY.—2 P.M., Mr. C. H. Hayton: Throat Operations. 2.30 P.M., Dr. J. B. Alexander: Medical Out-patients. Dr. W. Jenkins Oliver: Skin Cases. 5 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.

THURSDAY.—2.30 P.M., Mr. J. Bright Banister: Gynæcological Operations. Dr. A. J. Whiting: Medical Out-patients. Mr. H. W. Carson: Surgical Out-patients. Dr. J. Metcalfe: X Ray Department. Mr. N. F. Fleming: Eye Out-patients.

FRIDAY.—2 P.M., Mr. J. Howell Evans: Surgical Operations. 2.30 P.M., Dr. C. E. Sundell: Children Out-patients. Mr. E. Gillespie: Surgical Out-patients. Dr. Shanks: X Ray Department. 4.30 P.M., Mr. E. Gillespie: The Treatment of Paralytic Deformities by Orthopædic Methods. 5 P.M., Dr. F. L. Provis and Mr. T. H. C. Benians: Venereal Department.

SATURDAY.—10.30 A.M., Mr. W. E Tanner: Surgical Operations. 3 P.M., Mr. H. W. Carson: Visit to Surgical Wards.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, Marylebone, W.

MONDAY, Nov. 21st.—11 A.M., Dr. Goodall: Out-patients. 2 P.M., Dr. Moon: In-patients. 5.30 P.M., Lecture:—Dr. Goodall: Auricular Fibrillation and Auricular Flutter.

TUESDAY.—10 A.M., Dr. Parsons-Smith: Out-patients. 10 A.M., Dr. Price: In-patients. 2 P.M., Sir S. Russell-Wells: Out-patients.

WEDNESDAY.—10 A.M., Dr. Parkinson, and 2 P.M., Dr. Moon: Out-patients.

THURSDAY.—2 P.M., Dr. Price: Out-patients. Dr. Moon: In-patients. 6.30 P.M., Dr. Hamill: Out-patients.

FRIDAY.—10 A.M., Dr. Parsons-Smith: Out-patients. 2 P.M., Dr. Parkinson: Out-patients. 3 P.M., Dr. Parkinson: In-patients. 4 P.M., Dr. Goodall: In-patients.

SATURDAY.—10.30 A.M., Dr. Hamill: In-patients.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Nov. 24th.—4 P.M., Lecture:—Mr. H. Tyrrell Gray: Congenital Hypertrophic Stenosis of Pylorus.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 19, Leicester-square, W.C.

THURSDAY, Nov. 24th.—6 P.M., Chesterfield Lecture:—Dr. W. Griffith: Common Forms of Dermatitis.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Nov. 22nd.—4.30 P.M., Mr. F. H. Westmacott: Laryngeal Neuroses.

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 24, Acomb-street, Whitworth Park.

THURSDAY, Nov. 24th.—Dr. A. C. Magian: Pelvic Inflammation.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURE at Whitworth-street West Branch, Manchester.

FRIDAY, Nov. 25th.—4.30 P.M., Dr. Dougal: Ectopic Pregnancy.

ANCOATS HOSPITAL.

THURSDAY, Nov. 24th.—4.30 P.M., Dr. A. H. Holmes: "D.A.H." (Tachycardia, Its Ætiology, Treatment, and Prognosis).

UNIVERSITY OF SHEFFIELD—FACULTY OF MEDICINE. Post-Graduate Lectures and Demonstrations.

TUESDAY, Nov. 22nd. (At the Royal Infirmary).—3.30 P.M., Mr. E. F. Finch: Demonstration of Cases. 4.15 P.M., Dr. A. R. Hallam: X Rays in the Diagnosis of Diseases of the Chest.

FRIDAY. (At the Royal Hospital).—3.30 P.M., Dr. J. G. Wilkinson: Ear Emergencies. 4.15 P.M., Prof. J. S. C. Douglas: Serums and Vaccines.

MEDICO-PSYCHOLOGICAL ASSOCIATION OF GREAT BRITAIN AND IRELAND, 11, Chandos-street, Cavendish-square, W.

TUESDAY, Nov. 22nd.—3.15 P.M., Quarterly Meeting:—Dr. M. Hamblin Smith: The Medical Examination of Delinquents. Dr. H. Davies Jones: Forgetting.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.

A Course of Eight Lectures and Discussions on Problems of Public Health in Relation to Industrial Hygiene at the Lecture Theatre of the Institute.

WEDNESDAY, Nov. 23rd.—4 P.M., Lecture VI.:—Dr. R. Prosser White: Do We Neglect the Industrial Skin Sufferer? (With Lantern Demonstration.)

Appointments.

BARRON, H. T., M.D. Lond., has been appointed Clinical Assistant to the Skin Department at Westminster Hospital.

GEBBIE, N., M.D. Glasg., D.P.H., Medical Officer of Health for the Borough of Hyde, Cheshire.

HOOD, D. W. C., M.D. Cantab., Honorary Consulting Physician to the Royal Earlswood Institution for Mental Defectives.

St. Thomas's Hospital: **SLAUGHTER, H. L.**, M.R.C.S., L.R.C.P. Lond.; **McCLEAN, D.**, M.R.C.S., L.R.C.P. Lond; **WILLEY, H. L.**, M.R.C.S., L.R.C.P. Lond.; **TALLERMAN, K. H.**, M.R.C.S., L.R.C.P. Lond; **PHILLIPPS, F. A.**, M.B., B.Ch., Cantab; **BURRELL, E. M.**, M.R.C.S., L.R.C.P. Lond.; **HARTLEY, S.**, M.C., M.R.C.S., L.R.C.P. Lond.; **SPIRA, J.**, M.R.C.S., L.R.C.P. Lond., Casualty Officers and Resident Anæsthetists. **HAMILTON, C. K. J.**, M.B., B.Ch. Oxon.; **GRANGER, E. D.**, M.B., B.S. Lond.; **WHITELAW, A. D.**, M.R.C.S., L.R.C.P. Lond.; **BACK, G. A.**, M.R.C.S., L.R.C.P. Lond., Resident House Physicians. **KENDALL, G. M.**, M.D. Cantab., Resident House Physician for Children. **TRACY, G. D. C.**, M.R.C.S., L.R.C.P. Lond.; **LIANG, P. T.**, B.Ch. Cantab., D.T.M.; **HUMFREY, S. H. G.**, M.R.C.S., L.R.C.P. Lond.; **SQUIRES, F. V.**, M.B., B.Ch. Cantab., Resident House Surgeons. **BROCKMAN, E. P.**, M.B., B.Ch. Cantab., Resident Orthopædic House Surgeon. **CHURCHER, J. C.**, M.R.C.S., L.R.C.P. Lond., Resident House Surgeon for Ear, Nose and Throat. **MAXWELL, L. B.**, M.B., B.Ch. Cantab., Senior Obstetric House Physician. **CARDELL, J. D. M.**, M.R.C.S., L.R.C.P. Lond., Junior Obstetric House Physician. **LOW, W. A.**, M.R.C.S., L.R.C.P. Lond., Senior Ophthalmic House Surgeon. **SHAW, J. A. P.**, M.R.C.S., L.R.C.P. Lond., Junior Ophthalmic House Surgeon. **CAVENAGH, J. B.**, M.B., Ch.B. Oxon.; **WILLIAMS, B. W.**, M.R.C.S., L.R.C.P. Lond.; **HACKWOOD, J. F.**, M.R.C.S., L.R.C.P. Lond.; **WHITTING, C. E.**, M.R.C.S., L.R.C.P. Lond.; **SHIRES, B.**, M.B., Ch.B. Edin.; **PARSONS-SMITH, B. T.**, M.D. Lond., Clinical Assistants.

Vacancies.

For further information refer to the advertisement columns.

Altrincham General Hospital.—H.S. £175.

Bradford City.—Asst. Bacteriologist. £600.

Bradford City Municipal General Hospital.—H.P. and H.S. Each £350.

Bridgend, Glamorgan County Asylum.—Jun. Asst. M.O. £415.

Bridge of Weir, Consumption Sanatoria of Scotland.—Res. Asst. M.O. £200.

Brighton Education Committee.—Female Asst. Sch. Doctor. £500.

Brighton, Hove Hospital.—Res. M.O. £250.

Burslem Haywood Hospital.—Res. M.O. £200.

Bury Infirmary.—Jun. H.S. £150.

Cambridge, Addenbrooke's Hospital.—H.P. £130.

Canterbury, Kent and Canterbury Hospital.—Hon. Ophth. Surg.

City Dispensary, College-street, E.C.—Vistg. M.O. £52 10s.

Derbyshire County Council.—Asst. Sch. M.O. and Asst. Tuberc. O. £600.

Dumfries, Crichton Royal Mental Hospital.—Clin. Path. £400.

Durham, Richard Murray Hospital, Blackhill.—Res. M.O. £400.

Elizabeth Garrett Anderson Hospital, Euston-road.—Female Radiologist. H.P. Two H.S.'s. and Obstet. Asst. Each £50.

Frimley, Burrow Hill Sanatorium, &c.—Res. Med. Supt. £600.

Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Asst. H.S. £150.

Greenwich, Dreadnought Hospital.—H.S. £150.

Guildford, Royal Surrey County Hospital.—H.S. £150.

Hampstead General and North-West London Hospital, Haverstock Hill.—H.P., H.S., Cas. M.O. and Cas. Surg. O. Each £150. Also Dermatologist.

Ilford Urban District Council.—Asst. M.O.H. £650.

India, Countess of Dufferin's Fund.—Three Medical Women. Rs. 450 per month.

Ipswich, East Suffolk and Ipswich Hospital.—Res. M.O.

Iraq.—Two M.O.'s. 600 to 1000 rupees per mensem.

Lincoln County Hospital.—Jun. H.S. £150.

Liverpool Eye and Ear Infirmary.—H.S. £150.

Manchester, County Asylum, Prestwich.—Asst. M.O. £528 18s.

Manchester Royal Infirmary.—Asst. M.O. and Asst. Surg. O. Each £35. H.S. £50.

Margate, Royal Sea Bathing Hospital.—S. £200.

Middlesbrough, North Ormesby Hospital.—Hon. S.

Nottingham Children's Hospital.—Female Res. H.S. £180.

to medical and military literature, and was the author of "The Medico-Military Topography of the Persian Gulf and Euphrates and Tigris Valley," "The Causes and Cure of Army Drunkenness," "The Death March through the Khyber Pass," and several manuals relating to army medical organisation and service.

One of his fellow officers writes of General Evatt:

"Perhaps his most fruitful work was done in 1881, when he read a paper to the Royal United Service Institution on Army Medical Organisation in War, appealing for militia volunteer bearer companies, for larger staffs of field hospitals, for an army medical corps, officers and men together, for a central military medical school in London, so that military medical officers might be in touch with the leaders of the civil medical profession and hear from them of the advances they were making, for an army medical journal, for proper organisation of the medical corps for war. All these have since come. The more the autonomy of the medical corps is fostered, said Evatt, the more we shall rise to efficiency. I met him first when he was P.M.O. of the army in Hong Kong. In his first year there Kowloon got a good water supply. In his second, the army took over an hotel at the Peak, 1700 feet above the sea, as a convalescent barracks, to give the women, children, and men of the army change in the hot season from the oppressiveness of quarters at the sea level. In his third year the soldier got a third shirt. How, he said, can a man change his sweaty shirt at night unless he has three; one will be at the wash. It is difficult nowadays to realise how different he was from other senior medical officers, how helpful to junior officers who wished to work. Primarily, perhaps, he was a philanthropist, but his education and employment made him seek the benefit of the nation by improvement in the training and position of the medical profession, which owes him gratitude."

Sir George Evatt married in 1877 Sophie Mary Frances, daughter of W. W. Raleigh Kerr. The loss of their only son at Mons clouded the end of his life, otherwise rendered happy by the way in which the Royal Army Medical Corps made good during its great ordeal.

Medical News.

UNIVERSITY OF CAMBRIDGE.—Dr. G. B. Batten, Dr. I. S. Hirsch, Dr. E. R. Morton, and Dr. C. W. S. Saberton have been approved for the Diploma in Medical Radiology and Electrology.

UNIVERSITY OF OXFORD.—Mr. E. G. T. Liddell, B.M., B.Ch., Trinity College, formerly senior demy of Magdalen College, has been elected to a Fellowship at Trinity College. Mr. M. H. Mackeith, B.M., B.Ch., of Queen's College, has been elected to a Fellowship at Magdalen College, and has been appointed demonstrator in human anatomy. Dr. E. W. Ainley Walker has been elected a member of the General Board of the Faculties, as a representative of the Faculty of Natural Science.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At a meeting of Comitia of the Royal College of Physicians on Oct. 27th, and of the Council of the Royal College of Surgeons on Nov. 10th, diplomas of L.R.C.P. and M.R.C.S. were respectively conferred upon 77 candidates who have passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the by-laws. The following are the names (including 20 women) and medical schools of the successful candidates:—

M. T. Ahmed and S. Annecke, Guy's; Helen R. Ashton, London; T. J. D. Atteridge, St. Bart.'s; Mary J. Ayrton, Cambridge and Charing Cross; A. H. Bean, Univ. Coll.; J. H. Blair, Kingston (Ont.); J. G. B. Brass, St. Louis and London; *H. F. Brice-Smith, Cambridge and Middlesex; E. E. L. Burnier, Lausanne; Linda Catmur, London; W. E. R. Coad, Toronto and Univ. Coll.; W. E. Cody, Bombay and St. Bart.'s; Nancy M. Coutts, Royal Free; P. G. Cumming, Manchester; E. C. Curwen, Cambridge and St. Thomas's; P. T. Davidson, Middlesex; Edith M. P. Davies, Royal Free; Muriel A. M. Davies, St. George's; A. H. Douthwaite, Guy's; H. S. Drabble, Sheffield; C. T. J. N. Drobig, St. Thomas's; H. O. Eksteen, Guy's; A. H. El Ramli, Cairo and Liverpool; E. W. Evans, Birmingham; V. Feldman, Univ. Coll.; L. R. Fifield, London; E. C. H. Foreman, Univ. Coll.; E. Gallop, J. E. Gardner, and C. M. Gwillim, St. Bart.'s; C. B. Hawthorne, Cambridge and Birmingham; Margaret Haywood, Royal Free; Marjorie B. Hubert, St. Mary's; *J. W. Hunt, Toronto and London; E. R. Jagger, Manchester; A. V. Johnson, Cambridge and Birmingham; Eva M. Johnson, Univ. Coll.; David John Jones, Cardiff and Westminster; Dilys Menai Jones, Cardiff and Univ. Coll.; Gladys H. E. H. J. Jones, London; R. O. Jones, Liverpool; E. J. L. Jones-Evans, St. Thomas's; G. Kinneir, St. Bart.'s; F. C. Lewis, Liverpool; W. E. Lloyd, St. Bart.'s; I. B. McCann, Guy's; Elisabeth E. McCulloch, Liverpool; A. Maude, Manchester; E. O. Morrison, Cambridge and St. Mary's; J. B. G. Muir, Middlesex; H. W. L. Nichols, London; F. A. Pickworth, Charing Cross; †Ruth W. Plimsoll, Royal Free and St. Mary's; Enid Mary Powell, Cardiff and Charing Cross; F. W. M. Pratt, Durham and St. George's; J. A. Prichard, Bristol; Philippa P. Pughe, Univ. Coll.; W. G. Roberts, Liverpool; A. T. Rogers and I. Rosenberg, Guy's; J. J. Rowlands, London; A. R. Rutnam, Middlesex; Elaine M. K. Salmond, Royal Free; L. Segal, Charing Cross; A. I. Solberg, Leeds; A. E. Strawbaum, Cape and Guy's; R. O. Swaine, Middlesex; D. R. Thompson, London; Helen C. Tompson, Royal Free; Nellie Vaus, Westminster; C. E. Whitting, Cambridge and St. Thomas's; A. B. Whytock, Kingston; B. W. Williams, St. Thomas's; W. H. Williams, Charing Cross; Beryl Wischam, Calcutta and London; J. R. Wright, Manchester; and Greta I. Yeoman, St. Mary's.

* Diploma of M.R.C.S. previously conferred.
† Diploma of M.R.C.S. alone conferred.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At an ordinary council meeting, held on Nov. 10th, Sir Anthony Bowlby being in the chair, diplomas of membership were granted to 70 candidates.—Regulations for the F.R.C.S. with Ophthalmology were approved and adopted. The examination, which will be held in June and December, comprises anatomy, physiology, and optics in their relation to ophthalmology; clinical and pathological ophthalmology, and ophthalmic operations. It consists of (*a*) two written papers, (*b*) a written and viva voce examination on patients, (*c*) operations, (*d*) viva voce examination upon pathological and anatomical specimens and upon ophthalmology in general. Candidates must be Fellows or have passed the second professional examination for the diploma of Fellow. They must produce evidence of having held the office of clinical assistant, house surgeon, or registrar for a period of two years at a recognised ophthalmic hospital or in the ophthalmic department of a recognised general hospital. The last-named conditions may be modified in the case of a candidate (*a*) who holds, or has held, the appointment of (assistant) ophthalmic surgeon, (*b*) who has carried out original investigations, (*c*) who has written a thesis or published work, (*d*) whose studies or practice have extended over a prolonged period. The fee for readmission is £10 10*s*. A candidate who passes the examination will receive a certificate entitling him to describe himself as "F.R.C.S. (with Ophthalmology)."—The President reported that he had signed and attached the College seal to the agreement between the War Department and the College relating to the custody by the College of the Army Medical War Collection of pathological, orthopædic, and other specimens.—A letter was read from the clerk to the London County Council calling attention to a scheme for the welfare of blind persons in London and the setting up under the scheme of a central council for the London blind, for advisory and other purposes. Mr. J. Herbert Fisher, F.R.C.S., was appointed as the representative of the College on this central council.—The President reported that the Thomas Vicary lecture on a Glimpse into the History of the Surgery of the Brain would be delivered by Sir Charles Ballance on Thursday, Dec. 8th, at 5 P.M., and that the Bradshaw lecture on the Operative Treatment of Malignant Disease, its Possibilities and Limitations, would be delivered by Mr. H. J. Waring on Wednesday, Dec. 11th, at 5 P.M.

At the Primary Examination in Anatomy and Physiology for the Fellowship, held from Nov. 1st to 11th, 151 candidates presented themselves, of whom 35 per cent. were approved (including four women) and 65 per cent. were referred. The following are the names and medical schools of the successful candidates:—

W. C. Abell, Leeds; N. F. Adeney, Cambridge and St. Mary's; J. C. Ainsworth-Davis, Cambridge and St. Bart.'s; Annie Anderson, Aberdeen and St. Mary's; J. B. Barnett, Birmingham and Middlesex; A. P. Bertwistle, Leeds and St. Mary's; D. P. Bhargave, Lucknow and London; H. C. Brayshaw, Edinburgh and St. Mary's; L. G. Brown, Oxford, London, and Middlesex; W. G. S. Brown, Cambridge; H. Bruce, Leeds; W. K. Connell, Glasgow; J. A. Currie, Guy's; V. W. Dix, Cambridge and London; J. Elgood, St. Bart.'s; F. N. Foster, Leeds; F. P. Fouche, Edinburgh; A. J. Gardham, Univ. Coll. and Middlesex; W. H. George, Cardiff and London; C. S. Gideon and Katharine A. C. Gillie, St. Mary's; J. D. Grierson, Edinburgh; K. W. Heritage, London; E. Holmes, Leeds; G. H. G. Jackson, Cambridge and London; J. A. James and Gwladys R. Llewelyn, Bristol; N. P. L Lumb, St. Thomas's and Middlesex; A. G. Lumsden, Aberdeen; A. C. McAllister, King's Coll., Middlesex, and St. Mary's; J. McCormack, Belfast and St. Mary's; J. R. McDonald, Edinburgh and London; N. Makar, St. Mary's; W. A. Mill, Guy's; C. I. N. Morgan, St. Bart.'s; J. D. R. Murray, Cambridge and Middlesex; J. R. Nicholson-Lailey, Bristol; Constance M. Ottley, Oxford and London; K. O. Parsons, Guy's; A. A. F. Peel, Oxford; R. S. Scott, St. Bart's.; H. W. Symons, Leeds and London; G. L. Thompson and instincts to do). However, that may be, if we take song, fiction, drama, art, &c., as play exercise of emotion there is no doubt that the sex motif is always well represented.

These considerations seem to me to point to the conclusion that the energy of the non-sexual impulses is occupied ab origine in the proper functions, while sexuality is the only important source of a surplus of free adaptable psychic energy. This has equal importance for the psychopathologist and the anthropologist, and I cannot see any inherent improbability in Freud's empirical findings. For the same reason, and because of the characteristics pointed out above, the sexual instincts appear to be much more significant for psycho-pathology than the relatively stereotyped and canalised impulses that are vital to the individual.

Sex in Social Life.

One of the biological values of the social habit is that it ensures the meeting of mates at mating season, and thereby makes less demand upon the sexual impulse. There are two psychic pre-conditions of social life: (*a*) That individualistic instincts should be adjusted harmoniously—sex rivalry is the usual determinant of cleavage—and (*b*) that members of the community should possess a margin of interest beyond that fixed in the service of their individual vital needs. This adaptable surplus may theoretically proceed from any of the instincts, or may be unspecialised ab origine. It seems more probable, however, that it attains its functional employment via the natural (instinctive) channels by a play adaptation. One aspect of the problem is, what proportion makes use of sexual channels, and how?

That sex is in some way the crucial factor in communal life might be suspected from the remarkably clear-cut way in which existing societies may be classified on a sexual basis, and from the definite divergence of type and tendency shown by the groups so discriminated. Of course, the factors of original endowment and adaptability of instinct are of overwhelming importance when comparing the habits and mode of life of insect and mammal; but the point to which I wish to draw attention appears quite clearly within the group of mammal societies. All I desire is to call attention to three types of gregariousness and to show a coincidence between their "culture tendency" and their sexual organisation. (1) Many species form temporary associations, as, e.g., during migrations, which have a unity beyond that of similar reaction to similar circumstances, which may even group members of different species. Such associations achieve none of the permanent constructive purposes of social life; their integration usually gives way on the return of the interests of the mating season. They are asexual communities. (2) The most conspicuous type of community is the sexual unit, the family, where one sex is represented by only one active member. (3) Societies proper, where several families live permanently together with common interests pursued in common.

The first type is not important except as a possible origin for more elaborate forms. From the contrast between the next two we can form some idea of the significance of sex for society. Especially is this apparent when we observe that man is the only species that has truly created a society of the latter type, and that even yet he cannot be said to have established any form whose harmony with his own nature guarantees its permanence. Of the second (familial) type of community there are two distinct forms: the "hive" centring round one functional female, and the "herd" centring round one male. Only insect fecundity can render the former possible; in mammals the reproductive function claims most of the energy of most of the females. Both types of community waste the male sex, by killing, or expelling to live solitarily, most or all of their males. The "herd" consists of sexual individuals, although (after elimination of males and owing to female fecundity and to the power of organic specialisation) the insects can still set aside for social purposes a class deprived of the impulse leading to sex rivalry, while yet retaining the constructive and unselfish "maternal" instincts. This (familial) type of social organisation does not require or achieve (in any phylum) any control of jealousy, any harmonisation of sex rivalry; queens and bulls alike fight to the death or split the community. The stereotypy of insect instinct of course forbids progress here, but the herd has shown an equal incapacity.

For both of these forms of "family" community, then, the unifying biological purpose and the social organisation is sexual. In this respect and in the absence from the "herd" of sexually functional but underfunctioning individuals, they differ from human society, a circumstance agreeing with Freud's Theory of Culture.

Imperfect Specialisation of Mammals.

To obtain services similar to those rendered to their communities by insect "workers," mammals (owing to limited fecundity and long infancy) must utilise their males. In one sense this is an economy, but the material seems to be refractory, perhaps owing to lack of maternal instinct. Again, in default of the unique insect capacity for organic specialisation, this must take the form of an adaptation of interest, which at best can only be gradually and partially accomplished by upbringing. The work or culture interests must be imposed, artificial, and always making headway against the counter-attraction of primitive sex interest and the temptations of play and repose. For the same reason (imperfect specialisation) mammalian communities cannot transcend the "family" organisation without overcoming and perpetually resisting the disruptive tendency of sex rivalry.

Survival Value of Social Habit.

Both of the psychic preconditions of society-building—the securing of harmony and of surplus adaptable energy and interest—are thus bound up with the assimilation and utilisation of the reproductively irresponsible male sex, and the harmonious direction of their surplus energies into socially useful channels—i.e., the main problems of society are sexual problems. It cannot be argued that man's pre-eminence is solely due to his organic endowment, for without his social habits these would have little survival value. We must rather conceive that structural variations and social development have facilitated mutual growth by a process of organic selection.

Development of Intellectual Intercourse.

Though lacking the unity and stability of the "family" organisation, human society has gained the potentiality of variation and progress, and has, in addition, the advantage of utilising the entire species without mutilation or stereotypy of the individual. The combination of "family" or sexual units into a "social" unit, besides permitting an increase in the size of the community unhampered by reproductive considerations, introduces an important modification into the affective relationships of its component members. It substitutes for reciprocity of interest, based on complement of function, a parity or identity of interest that is, to my mind, the basis of intellectual development. For the development of language, and hence of conceptual intellect, intercourse is necessary between individuals with the same interest in the same objects, who have an identical, not a reciprocal affective world outlook. Language and thought are strictly coöperative activities; they can only be developed between companions with the same objective interest. Complementary interest reduces intercourse to a minimum, indeed it is a specialisation of interest that divides, that prohibits understanding. Of course, the mutual interest of the sexes in each other carries no possibility of thought or language development.[1] The conditions of the origin of language and thought are the intercourse and coöperative activity of a number of individuals with objective interests, which interests are at once adaptable and similar in tendency. These conditions are only fulfilled in a society as here defined and studied.

We conclude, then, that the social habit has a sexual value, that its evolution has been through the sexual to the polysexual unit-organisation, that its fundamental condition has been the limitation and adjustment of the sex interest and claims. If we still cannot allow that the impulses of sociability have a sexual origin, and that diverted sex interest is the motive of culture, we must still recognise that the development of society in all its diverging lines centres round the sex instinct, which, if not its stimulus, plays a no less significant part as its opponent. In opposition, if not in conjunction, sex is the basis of society. As environment, without directly influencing organisms, can yet by selection ensure their adaptation to itself, so sexuality even without acting as a creative interest, may impress itself upon every institution of every society. Sex regulation is the prime necessity of social life; what wonder that surviving forms of society should bear such traces of this adaptation that it is difficult to say whether they have been moulded by or moulded upon the sex instinct? In either case sex is the crucial factor for sociology, and institutions such as exogamy attest the difficulties overcome.

---

[1] Though there is reason to believe sex interest to be highly adaptable, yet it is, emphatically, only highly adaptable under conditions of obstructed functioning. In its simple form, with the "vital series" unimpeded, no transformation or deviation is conceivable from the stereotyped instinctive channels. The tension of sex interest (potential stimulus to thought and activity) is then inconstant, and even when high, unfavourable to indirect and elaborate expression as in thought activities, since it tends essentially to emotional expression. Furthermore, sex has no variety of common external objects and sequences which serve as the bases for general ideas and require intellectual understanding rather than practical mastery: its practice requires no elaborately devised technique and certainly no coöperative labour. These circumstances, which are lacking in the sphere of simple sexuality, are the conditions of the development of intellect, and it is probably appreciation of this fact which makes Freud's attribution of culture to a sexual energy-source seem so incredible. It should be understood, however, that the recognition of the above-mentioned considerations is not incompatible with the psycho-analytic position.

The Long Fox Lecture.—The tenth Long Fox Lecture will be delivered on Monday, Nov. 28th, at 5 P.M., in the Physiological Theatre of the University of Bristol, by Mr. E. W. Hey Groves, who will take as his subject the Repair of Bone Injuries. The chair will be taken by Sir Henry Gray.

Bristol Medical School: Annual Dinner.—This dinner will be held on Monday, Nov. 28th, at the Grand Hotel, Bristol, at 7 for 7.30. Sir Henry Gray will be the guest of the evening, and Mr. W. R. Ackland will preside. It is hoped that old students will make a special effort to be present. The speech list is to be shortened, so as to allow old friends time to talk to each other. Tables of six or eight can be arranged on application to the Secretaries, Messrs. R. S. Statham and J. A. Pritchard at the Medical School.

Scalp Ringworm in Bristol Schools.—The Bristol Medical Committee has organised a series of meetings at which it has been addressed by the medical officers in charge of the various public services. At a recent meeting Dr. R. A. Askins, principal school medical officer, spoke of the urgent need for routine microscopic examination of children convalescent from scalp ringworm, prior to their readmission to school. The committee has therefore decided to inform every medical practitioner within the city that Dr. Askins has made arrangements for a microscopic examination of these cases on the completion of treatment.

Infirmary Training for Nurses.—The Steyning board of guardians, at a meeting on Oct. 25th, discussed the desirability of the separation of the infirmary from the workhouse proper. The union, under the care of the board, includes the town of Hove, with a population of 46,519, and controls an area with a total population of some 111,000. One reason for the proposed separation is that in order to comply with the curriculum approved by the General Nursing Council the guardians will have to provide the means for improved training for nurses. The present training received by probationers is regarded as inadequate for the after-treatment of acute medical and surgical cases. A year ago a theatre was fitted up for minor operations, and arrangements were made for the reception of paying patients requiring such operations. A subcommittee has now been appointed to prepare a tentative scheme for ensuring the adequate training of nurses.

Certification Fees in Ireland.—The Irish Medical Committee has been informed by the Irish Insurance Commission that it will be necessary in the immediate future to reduce materially the fees paid for certification under the National Health Insurance Act. At the beginning of 1920 the remuneration was increased by 40 per cent., as a temporary bonus, and as panel fees in Great Britain have now been reduced from the temporary figure awarded two years ago, the Treasury thinks fit to reduce similarly the remuneration in Ireland. It is not considered likely that the Irish Medical Committee will, on behalf of the profession, give its consent to reduction, and for any disturbance of work arising therefrom the Treasury will be responsible. If a reduction is made it will press particularly heavily on country doctors, many of whom have been deprived of a large proportion of their salaries by the diversion of the State health grants to extraneous purposes.

Public Health in Aberdeenshire.—Conferences have recently taken place regarding the coöperation of the medical services in Aberdeenshire between representatives of Aberdeen County Council, Aberdeenshire education authority, the various district committees, the town councils, managers of joint hospitals, and the County Nursing Association, along with the various medical officers of these bodies. The representatives were of the opinion that a scheme of coördination of the public health services was highly desirable with a view to the prevention of overlapping and waste. The medical officers of health in the county and the burghs were asked to consider the question and submit a draft scheme to the committee. At a meeting of the medical officers there was some difference of opinion, less as to the desirability of coördination than as to the means of bringing it about. Dr. N. Davidson (M.O.H., Peterhead), who was appointed to consider the memoranda drawn up by the two parties, stated that both views submitted were laudable, but that the medical services of the county should be placed upon a broader basis with a view to obtaining progressive unification. At another meeting the committee decided to send a communication to all the district nursing associations, intimating the amount of the grants available for the services of nurses under the several county schemes. It was also decided that the education authority should endeavour to come to an arrangement with local authorities for provision of facilities at their hospitals for the cleansing of verminous children, clothing and bedding.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, W.

Thursday, Nov. 10th.—At 4 P.M. a Special General Meeting will be held to consider the Annual Report of Council.

List of probable papers:—K. Sassa: (1) Observations on Reflex Responses to the Rhythmical Stimulation in the Frog. (2) On the Effects of Constant Galvanic Currents upon the Mammalian Nerve-muscle and Reflex Preparations (communicated by Prof. C. S. Sherrington, P.R.S.). E. Ponder: The Hæmolytic Action of Sodium Glycholate (communicated by Sir E. Sharpey Schafer). Dorothy J. Lloyd and C. Mayes: The Titration Curve of Gelatine (communicated by Prof. F. C. Hopkins). D. H. de Souza and J. A. Hewitt: Idio-Ventricular Periodicity (communicated by Prof. W. D. Halliburton).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Wednesday, Nov. 23rd.

OCCASIONAL LECTURE: at 5 P.M.

Dr. Gustave Monod: Syphilis of the Stomach. A Discussion will follow in which Dr. A. F. Hurst, Dr. McNee, Mr. Herbert Paterson, and Mr. A. J. Walton will take part. There will also be an Exhibition of Specimens.

MEETINGS OF SECTIONS.

Tuesday, Nov. 22nd.

MEDICINE: at St. Thomas's Hospital, S.E. 1.

Tea at 4.15 P.M. Meeting at 4.45 P.M.

Clinical cases will be shown. Demonstration of Estimation of Basal Metabolism. Demonstrations of Methods of Estimating Liver Insufficiency and of Estimation of Blood-sugar.

Thursday, Nov. 24th.

UROLOGY: at the Cancer Hospital, Fulham-road, S.W. 3, at 2.30 P.M.

Operations by Sir Charles Ryall and Mr. Jocelyn Swan at No. 1, Wimpole-street, at 8.30 P.M.

Discussion on "Renal Function Tests."

Short Opening Papers will be read by: Mr. John J. Everidge, Mr. J. Swift Joly, Mr. J. B. Macalpine, Dr. MacLean and Mr. Cyril Nitch, Dr. Mackenzie Wallis and Mr. Girling Ball.

Sir Cuthbert Wallace, Dr. Langdon Brown, Mr. Frank Kidd, Dr. Marrack, Mr. G. E. Neligan, Mr. A. E. Webb-Johnson, Mr. A. Clifford Morson, and others will take part in the Discussion.

Friday, Nov. 25th.

STUDY OF DISEASE IN CHILDREN, at 5 P.M. (Cases at 4.30 P.M.)

Exhibition of Cases, &c.:—Miss Eva Morton: Report on a Fatal Case of Bullous Eruption. Other cases will be shown.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.

Paper: Dr. J. P. Kinloch: Metabolism in Fevers.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Nov. 21st.—8.30 P.M.: Discussion on "The Arseno-Benzo Treatment of Syphilis." Introduced by Lieut.-Col. L. W. Harrison, followed by Prof. H. Maclean, Dr. J. W. McNee, Dr. R. L. Mackenzie Wallis, Dr. Henry MacCormac, and Mr. C. H. Mills.

ROYAL SOCIETY OF ARTS, John-street, Adelphi. W.C.

Wednesday, Nov. 23rd.—8 P.M., Prof. J. A. Fleming: The Coming of Age of Long-Distance Wireless Telegraphy and Some of its Scientific Problems.

Friday.—4.30 P.M., Mr. A. H. Ashbolt: An Imperial Airship Service.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

Monday, Nov. 21st.—2 P.M., Mr. Addison: Demonstration of Cases (Surgical Wards). Dr. Scott Pinchin: Medical Out-Patients. Dr. Morton: X Ray Department. Dr. Simson: Diseases of Women. 5 P.M., Dr. Arthur Saunders: *Functional Dyspepsia* (Lecture).

Tuesday.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations and Visit to Wards. 11 A.M., Dr. McDougal: Electrical Department. 12 noon: Mr. Sinclair: Appendicitis (Lecture). 2 P.M., Dr. Burrell: Medical Out-patients. 2.30 P.M., Dr. Pritchard: Demonstration of Cases (Medical Wards). Mr. Tyrrell Gray: Visit to Surgical Wards. 5 P.M., Dr. Scott Pinchin: Differential Diagnosis of Pulmonary Tuberculosis (Lecture).

Wednesday.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 12 noon, Mr. Simmonds: Demonstration of Fractures, &c. 2 P.M., Mr. Gibb: Eye Department. Mr. Donald Armour: Visit to Surgical Wards. 5 P.M., Dr. Owen: Diagnosis and Treatment of Renal Disease (Lecture).

Thursday.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. MacDonald: Surgical Out-patients. Mr. Donald Armour: Operations. 2.30 P.M., Dr. Arthur Saunders: Visit to Medical Wards. 5 P.M., Dr. Simson: Modern Developments in the Management of Labour (Lecture).

1000 births. The birth-rate is lower than in either of the three preceding years 1916–18, in which the ratios were 32·30, 33·46, and 31·02 respectively. The death-rate (24·16) is higher than in either of the same three years (20·44, 21·25, and 21·70), as is the infantile mortality ratio. Enteric fever (729 cases and 203 deaths) was less prevalent than in 1918 (1011 cases and 248 deaths), the mortality ratio being 5·2 per 10,000, as compared with 6·5 in 1918; nearly half the cases occurred at Port of Spain, where the disease was endemic throughout the year. Tuberculosis mortality (13·11 per 10,000) was less than in the three years preceding (15·4, 13·5, and 14·4 per 10,000); nearly half of these deaths (240 out of a total of 504) occurred in Port of Spain. Malaria was prevalent throughout the year, and the resulting mortality, 26·21 per 10,000, exceeded that of either of the three years preceding (17·35, 19·78, and 22·00). Anti-malarial measures were carried out in various districts, and a spleen census taken of 18,145 children in elementary schools: this showed a percentage of 7·60 enlarged spleens, a considerable improvement on the findings in 1913–15, when the respective percentages had been 17·91, 14·11, and 11·20. Ankylostomiasis (7·86 deaths per 10,000) was more prevalent than in either of the three preceding years (6·82, 6·39, and 5·56 per 10,000). The Central Board of Health recommended that it should be made a punishable offence "to deposit human excreta or to defæcate anywhere except in a properly constructed privy in any district within a quarter of a mile of any occupied building." Influenza caused 332 deaths, compared with 46 deaths in 1918 (8·6 per 10,000 compared with 1·1 per 10,000); there were also 1031 deaths from bronchitis and pneumonia (20·9 per 10,000) in 1919, compared with 738 (19·2 per 10,000) in 1918, due to the same epidemic. Dr. Lassalle concludes his report by emphasising the importance of (1) the elimination of mosquito-breeding grounds; (2) the provision of pure water and food-supplies; (3) the provision of proper sanitary conveniences; and (4) the prevention of soil pollution in the vicinity of houses.

LADY HENRY SOMERSET MEMORIAL.

IT has been proposed that the most fitting memorial for the late Lady Henry Somerset would be to place the Homes which she established, and to which she devoted her life, on a firm financial basis, free from every encumbrance that might fetter their usefulness. The work done in the Babies' Haven and Industrial Farm Village, at Duxhurst, near Reigate, is of the greatest national importance, but funds and accommodation are so badly wanted that those in charge are obliged to refuse a great many applications for admission per month. The Homes for Inebriate Women have proved equally invaluable; Lady Henry Somerset's perseverance, in the face of much pessimism concerning the possibility of reclaiming women drunkards, has resulted in the cure of 70 per cent. of victims received at the colony. The Duchess of Leeds, Lady Clarendon, and Lady St. Cyres point out in their appeal for funds that the expense of work done at Duxhurst would, but for the existence of these institutions, fall on the rate-payer in the shape of upkeep of workhouses, prisons, and reformatories. There are no endowments, and subscribers are urgently needed. H.M. Queen Alexandra takes a very personal interest in Duxhurst and has expressed the wish that this special appeal may meet with the highest success.

Donations and subscriptions should be forwarded to the Hon. Treasurer, Mr. Ernest J. Wythes, Industrial Farm Village, Duxhurst, near Reigate, Surrey.

JANE HALL MURRAY BED.

AN invalid's convertible bed, couch, chair, and bath-chair, invented and patented by Mrs. Jane L. W. Murray, was exhibited for demonstration at the College of Ambulance, 56, Queen Anne-street, London, W., on Oct. 26th before an interested audience. The combination is designed to allow invalids to have many changes of position without exertion on their part, and to enable them to be moved from their rooms or to be taken outside without requiring to leave their beds. The bed-chair rests on four wheels. It is convertible at will from a bed to a couch, from a couch to a chair, and from a chair to a bath-chair, and back again. The means for effecting these conversion movements are ingenious but simple, and the operations can be performed by an attendant from either side of the bed. The bed is fitted with other appliances for giving ease and comfort. The patient may be raised from the prone position to that of sitting up, by the elevation of a section. An attachment for holding a tray also forms a reading or writing desk. The legs and feet of the patient can be raised. Bearer handles enable the patient to be carried. A canopy with celluloid windows and a waterproof apron and sheet form part of the equipment.

The Murray bed appears to us to be a valuable addition to the means of transport of invalids; and especially of those who suffer from ailments forbidding movement. These patients can be wheeled into the open, conveyed from house to house, from home to hospital, whether the weather is wet or fine, or taken for a journey in a railway van without being moved from their bed. Applications for the apparatus may be made to Mrs. Murray, at Dundarach, Craiglockhart, Midlothian, Scotland.

THE BLIND AND SMOKING.

To the Editor of THE LANCET.

SIR,—There is a very general idea that blind people are quite incapable of enjoying tobacco. I always imagine this idea arises from the fact that when a smoker who can see is smoking in a train which plunges into a tunnel he quite loses his sense of appreciation for the brief period during which he is in darkness. Some years ago I used to travel very frequently through the long Merstham tunnel, and I remember having, over and over again, looked at the end of my cigar to make sure it was alight.

The failure to appreciate tobacco in the dark undoubtedly arises from the fact that sight is not only the most useful of the senses, but is the dominating sense, asserting itself over all the others. Once this dominating influence is lost the other senses assert their individuality and carry on their functions independently of their former master. I smoked a great deal before my sight left me. I smoke a great deal still, and I am pretty sure that I enjoy my pipe or cigar more than I used to. Though it is, of course, true that a blind man misses the delightful sight of the curling smoke, his increased appreciation of the flavour of tobacco in my opinion more than makes up for this. The men of St. Dunstan's who smoke—that is to say, the vast majority of St. Dunstaners—would, I am certain, almost unanimously agree with me, and so would many blind civilian smokers whom I know. A pipe-smoker keeps his pipe going very largely by the sense of sight, and at first pipe-smoking without the aid of this sense is apt to result in the constant letting out of the pipe or the smoking of it so furiously that the bowl gets almost red-hot. But this is only a phase, as are many other things which people do clumsily when their sight first leaves them, but in the case of which practice makes perfect.

With regard to the popularity of various kinds of smoking among blind people, I should say that the pipe is the least popular, probably for the reason that I have just given. Cigarettes, of course, are the most popular form of smoking among the blind, as they are among the rest of the population. Those who care for cigars, and can afford them, find just as much pleasure in them as others do in the pipe or cigarette.

I am, Sir, yours faithfully,
St. Dunstan's, Nov. 11th, 1921. ARTHUR PEARSON.

THE PATIENT'S STANDPOINT.

THE following account of a hospital, by a 32-months' patient, appears in the October number of the *King's College Hospital Gazette*:—

"A hospital is a collection of corridors and stairs supported by slippery floors and contributions. A ward is a room attached to a corridor. It contains nurses, beds, patients, and fresh air in large quantities. A bed has longitude but no latitude. Its real duty is to beautify the ward. To disarrange a bed is a criminal offence. It is a far, far better thing to have a tidy bed than to be comfortable. A patient is the victim of circumstances—a conspiracy between the doctors and hospital authorities. After he has bided awhile he realises why he is called a patient. A nurse is essential for the proper running of the ward. Her chief duty is to watch patients in order to wake them when asleep. . . . . A clinical thermometer is a morbid cold-blooded instrument which requires a hot-air bath twice daily. The radiant heat necessary is provided by the patient. A chart is a piece of paper clipped to a board hanging on your bed. It is provided so that specialists can play noughts and crosses with the students. Has often been mistaken for an underground railway map, but is really the life story of a thermometer set to music. . . . The medicine cupboard contains brandy and castor oil. Tremendous quantities of each are used. The brandy is used to camouflage the castor oil and is also used as a restorative when patients feel faint. No patient is ever allowed to feel faint! Screens are used by the nurses instead of Sandow's Developer and are considered part of their uniform when on duty. No nurse is allowed to take a screen with her out of the ward when off duty. Most screens do not screen. Night commences when the blinds are pulled down—day commences when the night nurses have finished their midnight meal. Old patients sleep in the daytime—it is quieter. Lockers are a hospital version of dining-room sideboards. Always placed so that a patient cannot get at them, and really provided to gratify the nurses' curiosity. Lockers do not lock!"

The comment, if caustic, is not wounding to any particular institution, for the picture is wilfully drawn out of perspective, and hospitals can be made homely without diminution of efficiency.

W. *R.* is thanked for his communication which will be brought to the attention of the writer of the note in question.

Notes, Short Comments, and Answers to Correspondents.

THE SIGNIFICANCE OF THE SEXUAL INSTINCT FOR ANTHROPOLOGY AND PSYCHO-PATHOLOGY.

BY IAN D. SUTTIE, M.B., B.CH. GLASG.

IT is still objected that Freud attaches undue importance to the sex instinct in his ætiologies and theories of "culture." A mere conflict of observation on this point would resolve itself in time, but since disagreement extends to the very method of study, it seems worth while to seek a point of view independent of either position. These considerations, therefore, though a priori, have the advantage of impartiality, and do not involve the imputation of motive to either of the disputing parties. As regards ætiology, the charge of exaggerating the pathogenic potentiality of sex seems to me to imply also that of ignoring the significance of other motives, such, for example, as fear. I find no basis for this charge; as Freud's psycho-pathology allots to fear the dominant rôle. This does not seem to be generally realised, even by Freud in defending himself, but it is so. Fear (of punishment, reproach, &c.) is at the root of every repression, an essential factor in the endopsychic censor, and of greater power than the material it ejects. Indeed, from an altered point of view—a standpoint intellectually, if not ethically, truer—it is possible to regard the censor as the disease, and fear, disgust, &c., as the pathological reactions. Psychoanalysis may, then, have misconstrued the signficance of sex, but it certainly has not ignored the self-preservative motives.

"Instinct of Self-Preservation" Strictly a Misnomer.

It is apt to be forgotten that sex is by far the most powerful single instinct, and this oversight is, perhaps, partially due to the misapplication of the term, "the instinct of self-preservation," which is frequently taken to mean an instinct in the strict sense, as, for example, the sexual instinct. It is obvious that there is no such thing as an instinct of self-preservation—that the term applies only to a biological category of behaviour, a descriptive abstraction, and not to any organised psycho-physical disposition capable of exerting all the energy of its many powerful components as one unified motive. On the contrary, the manifold interests and activities, which happen to subserve at certain times and in certain circumstances the general purpose of the preservation of the organism, have nothing in common beyond this ultimate result. For example, the defensive emotions fear, anger, and disgust are as essential to life as the nutritional impulses, yet are independent of and even incompatible with them.

Even McDougal apparently lends support to the fallacious method of classifying behaviour according to the biological function it seems to fulfil, and then seeking to substantiate that classification in the psychic and physiological spheres—to discover psychological mechanisms corresponding to these utilities. Simple impulses, appetites, and the reflexes are activities probably equally definite subjectively and objectively—as conduct and as psycho-physical dispositions—but that is because we have no chance of making an abstract and irrelevant (teleological) classification. There is no a priori reason for supposing the emotion of disgust, and its physical basis, for example, to be more closely associated with other defensive reactions than with the sex impulses which protect the race.

The Sex Instinct.

The sex instinct is itself complex, but relatively synthetised, and should be compared only with equally organised impulses. If this is done it will be found: (1) That it is an appetite, therefore, to some extent, independent of external stimulation, and at the same time positive, not avertive; (2) that it is late in appearing and later still in attaining fixation by function, being unique in its period of non-functional activity; and (3) that, unlike the vital activities which must be efficiently performed from birth (on penalty of extinction) the sex instinct seems dependent more on mind and less on automatic impulse, and to undergo a long and elaborate psychogenesis rendered possible by this circumstance. It is obvious that the impulses of vital functions can never be diverted from their goal (perverted or sublimated—the difference is one of value) while natural selection might permit the development of a considerable uncertainty in the sexual, or other spheres of activity, unessential to individual existence. (4) It appears to me to be true that of all powerful instincts the sexual is most extensively applied in play. Perhaps it may owe most to a development under this exercise (as Groos supposes other

LYMPHATIC PATHOLOGY.

A few points in general lymphatic pathology must next claim our attention as bearing directly on the subject in hand. Perhaps the most constant and striking result of obstruction of the cutaneous lymphatic system is papillary hypertrophy. It may occur from increased transudation without lymphatic obstruction, but, broadly speaking, it must be regarded whenever it is found as strong prima facie evidence of the presence of lymphatic obstruction. In my opinion, lymphatic obstruction is the primary cause of papillomata of all varieties. It is seen at its maximum in elephantiasis. In artificially produced lymphatic œdema of the rabbit's ear, as studied by S. C. Shaw and myself, it is the salient feature of the cutaneous changes. In Paget's disease of the nipple, which as I have shown is due to permeation of the skin lymphatics of the nipple, considerable papillary hypertrophy takes place. Another evidence of lymphatic obstruction is lymphangiectasis—dilatation of the lymphatic vessels in connexion with the obstructed part of the system.

Generally speaking, lymphatic obstruction is incompetent to produce papillary hypertrophy unless it is associated with increased transudation from the blood-vessels. In the classical experiment of Starling, when a cannula was introduced into a lymphatic trunk of the limb of an animal, no lymph flowed until the muscles were put into action or the veins also were obstructed. Then a copious flow occurred. Apparently the lymphatic conduits are idle luxuries except in an emergency. It would appear that if lupus is a lymphangitis, and especially if to the lymphatic obstruction thus created there is superadded a certain degree of venous obstruction, papillary hypertrophy will be produced. I shall be able to show you that it is a characteristic feature of the disease. A presumption is thus raised that venous obstruction with increased transudation is present in lupus. This proves to be the case, and I shall later discuss the mechanism of its production.

The intimacy of the relations between lupus and the lymphatic system attracted the attention of Leloir, who in 1888 published an important paper entitled "Le Lupus Vulgaire et le Système Lymphatique,"[1] of which it will be necessary to give a brief summary. He expressly states that he regards the alterations of the lymphatic system as secondary complications of the lupus. He first draws attention to the areas of local lymphatic œdema and pachydermatous skin which may be found near areas of lupus. He next describes, in the skin near lupus patches—especially of the ulcerative variety—acute or subacute attacks of lymphangitic œdema, or of reticular lymphangitis presenting the characters of erysipelas. Sometimes these attacks coincide with necrobiotic softening, or rapid interstitial absorption of lupus nodules. These attacks vary in acuteness and extent, and in the closeness of their resemblance to erysipelas. Most often on the face they assume the characters of the so-called strumous or white erysipelas. They may be afebrile or accompanied by pyrexia up to 38° to 40° C., with more or less definite febrile symptoms. Leloir distinguishes them from true erysipelas which may also attack the subjects of lupus. The lupoid pseudo-erysipelas is less acute in its course, and does not invade the hairy scalp. Its edge is less defined, and the swelling is as it were flattened out. It is often white.

In some cases after such attacks, crops of fresh tubercles appear in continuity with the original patch or in its neighbourhood, or even at a certain distance away from it. These secondary or metastatic eruptions may be either ulcerative or not. In other cases, as may be seen most clearly in the limbs, the tuberculous virus of the lupoid patch in the dermis extends by means of the lymphatic vessels, ascending thus towards the root of the limb. Thus are produced cord-like lymphangitic thickenings along the lymphatics presenting in their course tuberculous gummata and tuberculous enlargements of the glands. Ultimately the lung on the affected side may become tuberculous, an event signalised by the onset about a week after an erysipelatoid attack of a fresh febrile attack and the appearance of physical signs of apical tubercle. I shall later refer to the treatment of these interesting cases, which appear to have been first described by Leloir.

Leloir next deals with enlargement of the lymphatic glands as seen in lupus. These enlargements are, he states, a stage in the centripetal march of the tuberculous virus. He admits that non-tuberculous glandular enlargements may occur in lupus, from local irritation and secondary infections of the lupoid patch, but maintains that many of the enlarged glands bear to the lupus patch the same relation that the glands in secondary syphilis bear to the primary chancre, and that they are due to infection by bacilli from the lupoid patch. Leloir proved his point by experimentally producing tubercle in animals with material taken from enlarged glands in lupus patients. He showed that tuberculous secondary glands may occur both in the ulcerative and the non-ulcerative forms of lupus. He pointed out that the glands were not necessarily caseous, or much increased in size, that they might present only miliary tubercles, and hence often escape observation. On the contrary, especially in ulcerative lupus, the glands may become very large, may soften, and burst, leaving open sinuses.

Secondary glands may disappear by interstitial absorption or by sclerosis. The glands which remain small, indolent, and elastic (resembling secondary syphilitic glands) are more likely than the large suppurating glands to lead to pulmonary or general tuberculosis. Leloir believes that, to arrest the march of the disease, enlarged tuberculous glands observed in a lymphatic area where a lupoid patch is situated should be eradicated. He has several times seen phthisis begin a few days after fugitive enlargements of the lymphatic glands had appeared and subsided.

SPREAD OF LUPUS.

The absence of anastomotic communication, except by way of the fascial plexus, between the adjoining primary lymphatic areas of the skin prevents the direct spread of pathological processes along the skin by way of the lymphatic vessels. They can only spread by first descending along the lymphatics tributary to the fascial plexus, by then spreading in the plane of the plexus, and by re-ascending to the skin to invade adjoining primary lymphatic areas. It results that though the general trend of such processes is centrifugal, it takes place not by continuity, but by the appearance near the primary lesion of punctate skin nodules which may subsequently merge into it. This is the characteristic mode of spread of carcinoma and melanotic sarcoma. (Fig. 2.)

It is highly significant that the same peculiar mode of spread is seen in lupus. Treves (System of Surgery) distinguishes between the spread of the primary focus of lupus at its edge and the formation of fresh spots in the vicinity. Stelwagon also draws attention emphatically to this peculiarity of the disease. It is, I submit, determined in lupus, as in malignant disease, by the anatomical peculiarities of the lymphatic system. There is a further point of similarity between lupus and malignant disease. It is a peculiarity of the malignant growths which disseminate by permeation of the lymphatic system that the secondary deposits are nodular. I have shown that in carcinoma the secondary nodule is often formed by the extension of permeation from a permeated lymphatic into the arborescence of minute lymphatics which unite to form it. I think I shall be able to convince you that the nodules of lupus originate in the same way by the extension of lymphangitis into the initial arborescence of an infected lymphatic vessel. I believe I can answer the question "Why is lupus nodular?"

---

[1] Le Lupus Vulgaire et le Système Lymphatique (Radicules, Vaisseaux, Ganglions), by Prof. H. Leloir.

I have had no occasion to make use of the concept, "herd instinct," and have no space to deal adequately with it, though, as in some sense an alternative explanation, it must be noticed. As Trotter uses it (i.e., to correlate sociable feelings with social conduct) the notion may have some heuristic value, but the term certainly does not refer to any true or possible instinct in the accepted usage. As an induction in the phenomenal sphere of behaviour it is merely a descriptive abstraction, if not an essential proposition, which has been arrived at by a process similar to that responsible for the equally mythical "instinct of self-preservation." Here, as in this latter case, the economic ideal of induction demands a single psychological explanation for all social behaviour, for all communal organisations; and the uncritical imagination proceeds forthwith to supply a verbal one. Herd conduct is due to herd instinct, what more does one want to know? Nevertheless, a proper analysis of communal organisations throughout the animal kingdom displaying differences of sex relationships, organic desexualisation and other phenomena, bespeaks so radical a difference in the instinctive bond of union that we shall no longer feel justified in postulating a single instinct to supply an identical motive for modes of conduct really so dissimilar. Reasoning from these correlated divergencies of sex-relationship and social achievement, one should rather attempt to display the varying characters of societies as due to the varying constraints and adaptations they impose upon this fundamental and universal instinct, or upon those others of whose universal existence and power we have independent knowledge. In this way we can refer an indefinitely large proportion of social phenomena to the interplay of known motives, and refuse to allow any field to be pre-empted by such an hypothesis as that of herd instinct. The matter requires special discussion.

If my presentation appears dogmatic, disconnected, and one-sided I must plead considerations of space. My object is merely to advance certain considerations displaying the social and psychopathological significance of sex from a standpoint outside that of clinical (empirical) psychology.

INDUSTRIAL MICRO-BIOLOGY.

THE Cantor Lectures to the Royal Society of Arts, delivered at the end of last year by Mr. A. C. Chapman, F.R.S., on *Micro-organisms and Some of their Industrial Uses*, have now been reprinted as a small pamphlet (F. J. Parsons, Ltd., 329, High Holborn, London, W.C. Price 2s.). While there is little that is actually new in the lectures, the author has done considerable service by once more drawing attention to the vital dependence of industry upon science and the application of scientific facts and to the fact that this scientific study has lagged in this country. His essential thesis is that "as chemists we shall—for a long time at least—become more and not less dependent on the powers (both synthetical and analytical) of living cells, and that it behoves us to study carefully the conditions which affect the activities of these cells, and which may even induce them to function in one direction or another at will." He illustrates this and other points by a lucid discussion of the mechanism of alcoholic fermentation, the production of glycerine on a large scale by the fermentation of sugar, the use of moulds to convert starch into sugar, the biochemical production of citric, lactic, and other acids, the manufacture of vinegar, the bacterial production of acetone and butyl alcohol, and in a number of other processes described in less detail.

Production of Acetone.

The national importance of the correct interpretation and use of scientific facts is very well illustrated by the production of acetone. Prior to the war the acetone required was manufactured from the acetic acid derived from the destructive distillation of wood and was nearly all imported. The greatly increased demand (for cordite and aeroplane dope), and the restriction of outside supplies stimulated the practical development of a scientific fact known for many years. By means of the fermentative action of a special bacillus, which under suitable conditions can produce butyl alcohol and acetone from starch, it was possible to develop the production of acetone by this biochemical action on a commercial scale.

A subject of considerable interest to medical readers is the utilisation of yeast for human food. The author states that from 50,000 to 60,000 tons of pressed yeast are produced per annum in the breweries of the United Kingdom, the great bulk of which is in the nature of a waste product. He discusses the use of this dried yeast as a food product both for man as well as animals and some of the scientific difficulties which have been overcome. He points out the superiority of yeast extract over meat extract as regards the presence of accessory growth-promoting substances.

Potential Activities of Yeasts.

Very considerable emphasis is laid upon the extremely important scientific fact that the chemical activities of micro-organisms may be made to vary widely according to the conditions under which they are compelled to function. For a good many years the production of alcohol, carbon dioxide, glycerine, and succinic acid in roughly definite proportions has been regarded as a fixed and characteristic property of yeasts. This is due to the fact that yeast has always been studied under a certain set of conditions. By varying these conditions it has been found possible to increase the percentage of glycerine produced from the normal 3 to 7 or 8 per cent., and later, by further developments to as much as 36 per cent. In other words, by varying the environment the response of the yeast cell was so altered that the products of its action upon sugar was entirely varied and it was made to produce glycerine upon a commercial scale. The German army authorities organised a company which at one time was making by this process as much as a million kilogrammes a month.

Need for a National Institute.

Mr. Chapman concludes his lectures by pleading for the establishment of a National Institute of Industrial Micro-biology. Such an institution would serve for the systematic prosecution of original research, as a centre for the specialised training of men intending to devote themselves to the teaching of micro-biology and biochemistry, for the practical instruction of factory managers and technical employees, and as a source of supply to the technical industries of the necessary organisms in pure culture. It is difficult to think of any institution likely to be of more benefit to British industry, and, taking the long view, its establishment would be a real contribution to the prevention of unemployment.

PUBLIC HEALTH IN TRINIDAD AND TOBAGO, 1919.

THE report on medical affairs in Trinidad and Tobago during 1919, recently published, is submitted by Surgeon-General K. S. Wise, who took over the duties from Dr. F. A. de Verteuil in August. It is satisfactory to learn that difficulties such as have been encountered in regard to understaffing of the Colonial Hospital at Port of Spain are not likely to recur, as the staff has been strengthened on a liberal basis and in conformity with modern views. Accommodation is afforded for 310 patients, but during the year this number was almost constantly exceeded, the most numerous diseases treated being venereal affections (412), enteric fever (311), pulmonary tuberculosis (257), malaria (250), acute and chronic nephritis (240), and ankylostomiasis (208). Dr. R. Seheult, the resident surgeon, draws attention to the increase in cases of malignant disease during recent years, the admissions having risen from 38 in 1910–11 to 83 in 1919. The cancer deaths in the colony per 100,000 living have risen from 6·9 in 1898 to 33 in 1918. In a very large proportion of the cases admitted the disease was so far advanced as to render operation hopeless. It is suggested that there should be a wide distribution of leaflets giving a concise outline of the facts in connexion with the disease, and explaining the need for early treatment. At St. Ann's Lunatic Asylum the average number under treatment was 654; the percentage of recoveries was 30·76; of the 169 admissions 87 were male and 82 female, 73 were "labourers" (male or female), 32 were "of no occupation," 11 were housewives, and 11 servants. At the Leper Asylum the average number in hospital was 543, and the total number treated 686, the deaths numbering 57, or 8·3 per cent. of the number treated. Hypodermic injections of gynocardate of soda have been carried out by Dr. S. D. Stewart and others. Dr. Charles Howatson, the medical superintendent, considers that "although the general health of those thus treated appears to be much improved, any real improvement resulting therefrom cannot at present be said to be marked. In some cases stains and anæsthetic areas have been favourably affected. One patient who had great difficulty in using her fingers can now work with them as she had never done before. The treatment seems to be of more benefit to anæsthetic cases." At the St. Augustine Yaws Hospital there were 1455 admissions, an increase of 156 on the number for 1918; the number of individual *cases* was 857 (compared with 870 in 1918); the average duration of stay in hospital was 42 days, and the daily average number present 166. Arsenobillon, diarsenol, and neodiarsenol were used by intramuscular injection. Dr. J. A. Perez, medical superintendent, considers that the results on the whole have been very satisfactory. Out of 10,045 cases treated since salvarsan and its substitutes have been in use the percentage of recurrence has been only 4·8. Dr. E. Hamel Smith, reporting on the Yaws Hospital at Tobago, states that "the arsenobillon treatment gives good results."

Report on Health Conditions, 1919.

From a further report by Dr. C. F. Lassalle, Assistant Medical Inspector of Health, we learn that the population of Trinidad and Tobago in the middle of the year 1919 was estimated at 381,247, that the birth-rate was 30·1 per 1000, the death-rate 24·46, and the infant mortality ratio 155 per

These appearances leave no doubt that the giant cells arise from the proliferated endothelium of a lymphatic vessel.

We have not yet considered the appearances found in the subcutaneous tissue beneath the skin. They are scanty, but very significant. In the perivascular tissue accompanying a small artery and vein may here and there be seen linear collections of granulation tissue containing an occasional giant cell. From their situation we infer that these appearances result from the tuberculous infection and subsequent destruction of a comitant lymphatic. *Infection of* the subcutaneous lymphatics in lupus is not a rare phenomenon, and has been frequently recorded by Leloir and others. Here is evidence that lupus is not confined to the skin, and is not, properly speaking, a skin disease at all. The skin provides a portal of infection and a rich lymphatic plexus in which the initial stages of the disease are located, but the subcutaneous lymphatics are soon infected.

Infection of Fascial Plexus.—Their infection certainly implies infection of the fascial plexuses into which they run. Though in this case I cannot demonstrate it histologically, it was sufficiently shown by the clinical presence of lymphangitis of the trunk lymphatics. If, as I maintain, infection of the fascial plexuses is constant in lupus, the intractability of lupus to treatment aimed at the diseased skin is easy to understand. The scraping or even the excision of the diseased area of skin is merely the equivalent of mowing a bed of nettles, for the roots of the disease—the infected lymphatics of the subcutaneous tissue and the deep fascia—remain untouched to reproduce it.

CASE 2.—The second specimen was a small patch of lupus, about half an inch in diameter, on the upper arm of a little girl. It had apparently been ulcerated, but when excised it presented a central scarred area surrounded by a collarette of slightly raised, reddish, sub-epithelial nodules. I shall only describe the appearances found in the visible patch of lupus by saying that the papillæ were much hypertrophied, and that from the centre of some of the papillæ lines of granulation tissue representing destroyed lymphatics passed down to fuse with the subjacent lupus nodules composed of similar tissue. Some of the nodules tailed off below into stalks of granulation tissue running with the blood-vessels. Both these facts point to the origin of the nodules by proliferation of the related group of lymphatic capillaries.

We now pass to the conditions found at the growing edge beneath apparently sound skin beyond the furthest lupus nodule. From the granulation tissue "stalk" of this nodule a side branch of granulation tissue passes out obliquely and can be traced right up to a papilla of the adjoining skin, into which it is prolonged. Thus a Y-shaped arrangement is seen, the left limb thick and formed of typical lupus tissue, the right limb slender and represented by a chronically inflamed lymphatic. The whole arrangement is a diagram showing how a lupus nodule arises. The left half is completed, the right half is an outline drawing. The process is evidently spreading from the depth to the surface, for several of the skin papillæ within the area of the Y are normal and show as yet no lymphangitis. Further away from the edge, V- or Y-shaped cords of granulation tissue occur at fairly regular intervals in the superficial dermis over a distance of about one-tenth of an inch. Some of the skin papillæ are healthy, others show lymphangitis. This would not be the case if the disease were spreading in the plane of the papillæ. A fortunate section in this region shows one of the infected dermal lymphatics opening out like a stag's antler into about half a dozen infected lymphatics of origin which can be traced right into the centre of the papillæ, and their character of lymphatics thus proved. This particular section is a complete demonstration that in its early stages, before the picture has become blurred and confused by unlimited proliferation and nodule formation, lupus is a lymphangitis. We have before us not a complication of lupus, but lupus itself in the initial stage. Beyond this point the evidences of infection become indistinct, but they can be traced in skin papillæ situated one-eighth of an inch from the visible edge, and possibly a little further. Hypertrophy of the papillæ could be traced about the same distance.

Evidence of Subcutaneous Infection.—The condition of the deep fascia could not be directly investigated, but its lymphatics were certainly infected, for tuberculous lymphangitis of the trunk lymphatics was present.

CASE 3.—The third specimen investigated was a strip of tissue excised beyond the growing edge of a case of lupus erythematosus. I shall not detain you with the histology of this specimen. Papillary hypertrophy is absent. It showed upon the deep fascia a quarter of an inch beyond the furthest point of disease in the skin, a cord of round cells accompanying a blood-vessel. This case provides distinct microscopic evidence that the disease spreads in the fascial lymphatic plexus. I found similar evidence in another specimen of lupus of the forearm, but the evidence of disease in the deep fascia is scanty and difficult to get, for excised specimens rarely include this layer. The evidence justifies the conception of the nature and spread of lupus embodied in the diagram. (Fig. 2.)

Growing Edge of Breast Cancer.

There is a great similarity between the spread of carcinoma in the parietes and the spread of lupus, in its clinical as well as in its histological aspects. Let me briefly recall that a patch of lupus arising on the hand may give rise to a ring of satellite nodules, and may infect the trunk lymphatics, may cause enlargement of the bicipital, the axillary, and the supraclavicular glands, and may finally attack the corresponding lung, a sequence of events which is also seen in an epithelioma arising in the same situation. On the contrary, either lesion may remain purely local. The clinical evidence thus bears out my microscopic conclusions as to the general similarity between the spread of lupus and the dissemination of carcinoma. How should it be otherwise if both diseases spread—mainly by continuity though partly by embolism—in the lymph-vascular system? The anatomy of that system is the same whether the patient suffers from carcinoma or from lupus. It determines the direction of spread in spite of the fundamental difference between the pathological processes involved—permeation in carcinoma, proliferative lymphangitis in lupus. If my conclusions are accepted the similarities between lupus and carcinoma are seen to be neither superficial nor fundamental; they result from the simple fact that the two diseases use the same highways.

Causation of Vascular Congestion and Necrobiosis.

The destruction of the lymphatic vessels and their replacement by cords of tuberculous granulation tissue involves results of great moment for the blood-vessels. When the lymphatic vessels have been destroyed, the relatively thick and diffuse cord of granulation tissue which replaces them envelops and ensheaths the accompanying blood-vessels. Like all granulation tissue it tends to contract, and pressure is thus exerted upon the blood-vessels. At first the vein is chiefly affected, and a venous stasis is produced which reddens the affected area of skin. Increased transudation of blood fluid follows, and if this stage is sufficiently prolonged hypertrophy of the papillæ of the skin results from the combination of increased transudation with lymphatic obstruction. Thus the more chronic forms of lupus tend to assume a warty form. If, however, the tuberculous process is more rapid, venous obstruction, with its accompaniment of increased transudation, is only a fleeting phase. The pressure of the contracting granulation tissue soon affects the arterioles, restricts the blood-supply, and diminishes transudation. Under these circumstances we find, instead of warty hypertrophy of the skin, a failure of nutrition in the overlying skin and in the tuberculous tissue itself. Ulceration and caseous changes follow. The particular form which lupus assumes thus depends on the degree of pressure exerted on the blood-vessels by the contracting granulation tissue which forms around them as a result of the tuberculous lymphangitis of their comitant lymphatics.

TREATMENT.

It is in the surgical treatment of lupus that my observations seem for the present to find their practical application. It is very necessary to recognise the existence around the apparent area of lupus of a zone of apparently normal but really infected skin. Even in the chronic forms of lupus, this zone appears to be present. The knife of the surgeon must if possible circumscribe this area if he wishes to avoid recurrence. Even more important is it to recognise the fact that excision of the skin alone is an irrational procedure. It is almost certain that the underlying area of subcutaneous tissue is riddled with microscopic tubercle in the form of tuberculous lymphatics, and that a corresponding area of the lymphatic plexus upon the deep fascia is infected. Whenever possible, therefore —and it can be done in all cases of lupus of the trunk and extremities—an area of deep fascia at least as

ROYAL ARMY MEDICAL COLLEGE LIBRARY

Hunterian Lecture

ON THE

PATHOLOGY AND TREATMENT OF LUPUS

(LUPUS A LYMPHATIC DISEASE.)

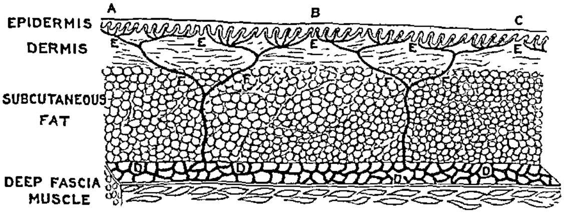
Delivered before the Royal College of Surgeons of England

BY W. SAMPSON HANDLEY, M.S., M.D. LOND., F.R.C.S. ENG ,

HUNTERIAN PROFESSOR; SURGEON TO MIDDLESEX HOSPITAL.

THE subject of my lecture lies on the border-line between surgery and dermatology, and my interest in it was first excited by a case referred to me for operation by my colleague, Dr. J. J. Pringle. I shall here deal only with the surgical pathology of lupus—that is to say, with those aspects of its pathology which have a direct bearing upon its operative treatment. It is no bad test of a lecture or paper to ask the author to write a précis of it on a visiting card. If to-night I had to submit to this test, my summary would run as follows: Tuberculous lupus is not a skin disease. It is essentially and primarily a disease of the lymphatics, a destructive lymphangitis of the parietal lymphatic system. I hope to show you that this conception is not a sterile one—that it has importance both immediate and prospective with regard to the treatment of this obstinate disease. Concerning the nature of the pathological process by which lupus spreads, various hypotheses have been held. It has long been admitted that a lupoid focus, wherever it is situated, may sooner or later infect the lymphatic system; but the phenomenon has always been regarded as secondary, *and no conclusion* has been drawn from it as to the essential nature of the morbid process at the primary focus of inoculation. From my point of view the essential event for the establishment of lupus is the inoculation of the bacillus into a cutaneous lymphatic vessel. The primary lesion is from the beginning a tuberculous lymphangitis, *at first of the dermal* lymphatics, but soon, of anatomical necessity, the process spreads to the subcutaneous lymphatics and to those of the deep fascial plexus. I shall try to show firstly, that upon the hypothesis that lupus is a destructive capillary lymphangitis, many hitherto unexplained phenomena of the disease become easy to understand; secondly, to place before you the direct histological proofs; and thirdly, to consider the bearings upon operative treatment of the knowledge thus acquired. Lastly, I may venture with all reserve to offer my dermatological colleagues a few suggestions in non-operative therapeutics.

FIG. 1.



To show the lymphatic arrangements of the skin. A schematic vertical section *of the skin and subcutaneous fat, with a small horizontal shelf of deep fascia* projecting forward from it. *Below this is muscle in vertical section.* AB and BC are two of the primary lymphatic areas of the skin. These areas measure one-third to half an inch in diameter, and the only lymph-vascular communication between them appears to be by way of the subjacent fascial lymphatic plexus DDDD which is seen on the flat. The lymphatic end-sacs of the skin-papillæ unite by groups of five or six to form small lymphatic vessels, which again unite in the superficial third of the dermis (plane of primary confluence *EEE) to form other lymphatic vessels, which pierce the dermis vertically and* unite just beneath it (plane of secondary confluence FFF) into a smaller number of vessels which run down through the subcutaneous fat to discharge into the fascial lymphatic plexus DDD.

LYMPHATIC ARRANGEMENTS OF THE SKIN.

The descriptions of the lymphatic arrangements of the human skin found in the text-books are meagre, and I have had to rely mainly upon my own observations, derived partly from lymphatic injections, but chiefly from the perfect natural injections of the cutaneous lymphatics which are sometimes seen in *melanotic sarcoma and in Paget's disease of the* nipple. The lymphatic vessels take their origin in the papillæ of the skin as blind finger-like end-sacs lined by endothelium. It is of importance for my present purpose to note that just as a lacteal is the central structure of an intestinal villus, so a lymphatic end-sac is the central structure of a skin-papilla. This fact permits of the identification of lymphatic vessels in sections of skin, no longer with probability, but with absolute certainty. As in a villus, the blood capillaries surround the central lymphatic. Just as the fingers of a glove unite in the palmar region, so *these lymphatic end-sacs join by small groups to* form primary lymphatic vessels. The analogy of the hand is imperfect, in that these primary lymphatic vessels are actually of smaller diameter than the end-sacs which unite to form them. The region where the end-sacs are uniting by groups may be called the *plane of primary confluence. I ask you to note particularly that it occupies the superficial third of* the thickness of the dermis, and produces in this region the false appearance of a plexus, the so-called sub-papillary lymphatic plexus. (Fig. 1.)

The deeper two-thirds of the dermis appear poor *in lymphatic vessels. Those which are seen run* more or less vertically downwards. Just beneath the dermis, in the superficial layer of the subcutaneous fat, these vessels unite by *groups to form* secondary lymphatic vessels which run along the fibrous septa of the skin and empty themselves *into the fascial* lymphatic plexus. Accordingly, just beneath the dermis, where this zone of secondary confluence is found, a pseudo-plexiform arrangement of the lymphatic vessels is seen. This false plexus was described by Arnold as the deep cutaneous plexus. The *fascial plexus into which the* cutaneous lymphatics discharge is a true plexus. It is a unity investing the whole body, offering no barrier to the unrestricted spread of infection, and lying upon or in the deep fascia. It discharges by trunk lymphatics into the cervical, axillary, and inguinal glands.

It will be noted that, according to the foregoing *account, the skin would appear to be divided into* independent lymphatic areas, whose only lymphatic communication with each other is by way of the fascial lymphatic plexus. The communications resemble those in a ship with water-tight compartments closed, but the plane in which they take place horizontally is a deep one—the bilge and not the deck. Judging by the size of the primary lesions in certain skin eruptions due to lymphatic obstruction, *confirmed by observations upon areas of skin* permeated by cancer, the primary lymphatic areas of the skin appear to be about one-third to half an inch in diameter. There is one other fact of lymphatic anatomy upon which I must insist—namely, that in close company with each small artery and vein, one or more often two comitant lymphatics are seen. Both in cancer and in lupus serious consequences to the blood-vessels arise from this close association.

deep fascia, not merely the skin, and to this end gamma radiation from screened appliances must be employed. Treatment must be guided by microscopic conceptions, not by clinical appearances, and *must be mainly directed to the invisible growing edge, to the neglect at first of the visible lesion.* A rationally planned course of radium treatment on these lines should be more effective than the purely empirical treatment hitherto employed.

CONCLUSION.

The facts I have here discussed are fundamental for the treatment of lupus. The most profound study of bacteriology and chemical physiology could not have revealed them. They are the product of morbid anatomy, a branch of medical science temporarily out of fashion and by many wrongly supposed to be dead. I venture to urge that a revival of interest in morbid anatomy is necessary to the balanced progress of medical science. Those who depreciate it have failed to realise the recent advances in its methods. Its former cheese-tasting methods are out of date. The awakening of geology came with the realisation of the fact that the strata of the earth are frozen history. Similarly the dead tissue with which the morbid anatomist deals, if systematically examined, provides him with biograph films of the morbid processes which took place during life.

In conclusion, I must express my thanks to the present and past directors of the Bland-Sutton Laboratories of the Middlesex Hospital, Prof. J. McIntosh and Prof. C. H. Browning, for the facilities they have afforded me.

The Relation OF CRIME AND DELINQUENCY TO HEREDITY, ENVIRONMENT, AND DISEASE.

A Lecture given to Teachers at the London Day Training College on Oct. 27th, 1921,

BY W. A. POTTS, M.A. CAMB., M.D. EDIN.,

PSYCHOLOGICAL EXPERT TO THE BIRMINGHAM JUSTICES; MEDICAL OFFICER TO THE BIRMINGHAM COMMITTEE FOR THE CARE OF THE MENTALLY DEFECTIVE.

FIFTY years ago a remarkable theory relating to criminals was put forward by Lombroso—namely, that criminals constituted a distinct class, who could be recognised as conforming to a particular type, shown more particularly by the shape and size of their heads. Moral character was to be measured with a foot rule. Indeed, the science of criminology was to be even more simple, for not only could criminals be recognised, but also the nature of their misdeeds; after careful inspection the murderer, the thief, and the prostitute could be determined. Although discredited at first, Lombroso's theory gradually won much support. It derived credit from Lombroso's previous sound work, and also from the fact that it contains a germ of truth. Intelligence and good conduct do bear some relation to the size and shape of the head. It is impossible to have normal intelligence in heads below a particular size. It is an advantage to have a big head up to a point, but a skull of unduly large circumference is almost sure to contain a large brain of inferior quality. Some facts of that nature have been established, and are useful, but they only help us to diagnose a few of our abnormal cases and do not lead to the fine and universal distinctions Lombroso claimed. This method of diagnosis of criminals is now discredited. The death blow was given by the late Dr. Charles Goring, who examined an enormous number of prisoners and published the result in his famous work, "The English Convict." He established the fact that the criminal belongs to no particular type, though he is usually inferior to his fellows in stature, physique, and intelligence—a fact very different from that which Lombroso claimed to have established.

HEREDITY.

There is no criminal type. Numbers of criminals are often found in the same family, but so far as heredity is concerned, that only means they have inherited poor intelligence, weak physique, and so on. Well-marked criminal types show nothing more nor less than the abnormal cranial configurations we are accustomed to associate with a small percentage of mental defectives, such as the microcephalic and scaphocephalic. These particular configurations do not occur in more than 10 per cent. of defectives. But recent investigations have even thrown doubts on the inheritance of mental defect, as such, in many cases where it appears in a direct line. In one sense mental defect is essentially an hereditary character, but sometimes what is inherited is not a bad brain, but an inferior development of the thyroid and other so-called endocrine glands to which great importance is now attached. A function of some of these glands is the stimulation of normal development, particularly of the brain in fœtal life. This, however, is a controversial subject on which I cannot enlarge here; it does, however, make us think more of environment, because some of these glands are very sensitive to environment, particularly to infection of all kinds. The endocrine glands are of special importance during pregnancy, so that if we would diminish delinquency, some of our energy must be devoted to the ante-natal clinic.

In confirmation of Goring's findings I would quote from Dr. Healy, the great American authority on delinquency: "There are many kinds of criminals with all sorts of traits, and one would urge great caution in speaking of them in any way as a single group."[1] Then he quotes approvingly from Goring: "The physical and mental constitution of both criminal and law-abiding persons of the same age, stature, class, and intelligence, are identical. There is no such thing as an anthropological criminal type." Reflection will show that in a criminal family the environment and training, or lack of training, must affect the issue. Although Lombroso's theory has been disproved, there is a school who would explain delinquency in almost as definite and precise a manner —looking upon crime as largely indicative of mental defect. They start with the statement, which is true, that mental defect is more common among the prison population than the ordinary population, but even if they go on to the extravagant statement that 10 per cent. of all prisoners are defective (a fact not proved if the standard of intelligence indicated in the Mental Deficiency Act, 1913, is taken) it is hard to establish their point. For a large percentage have ordinary intelligence, grading as ordinary that exhibited by an average person brought up in similar surroundings with a similar education. The extremist would seem to beg the question by saying that only a small amount of mental defect is necessary to constitute a criminal, or that criminal conduct is a proof of mental defect. In the last resort it can be called moral imbecility. But the term moral imbecile often seems to me a cloak for ignorance. Nearly all the so-called moral imbeciles I have examined were mental defectives; the remainder suffered from some defect in physique, training, or environment, or—more usually—a combination of such abnormal conditions. This does not mean that the term "moral imbecile" is not a useful classification, provided it is only put forward on rare occasions; nor does it mean that the moral imbecile must at the present time be treated otherwise than by letting him meet the usual fate of his criminal acts. He is sometimes too dangerous to society to be at large, and we are sometimes too ignorant to deal with him in any other way than by punitive detention. But this diagnosis and treatment should be reserved for a small number only.

[1] The Individual Delinquent. William Healy, A.B., M.D. London: William Heinemann. 1914. P. 161.

Histological Evidence.

There is much histological evidence of the intimate relations of lupus to the lymphatic system, and some histologists have maintained, though they could not prove, that the disease spreads by the lymphatics. It is commonly stated that in lupus there is a downgrowth of the interpapillary cell columns of epithelium. This fallacious observation is a testimony to the occurrence of papillary hypertrophy. The interpapillary cell columns are passively stretched and then laterally compressed by lymphœdema of the intervening papillæ. Dilated lymphatics—the result, evidently, of lymphatic obstruction elsewhere—are frequently described. Time forbids me to linger on this subject, or to summarise the mass of literature connected with it.

Failure of Lupus Carcinoma to Disseminate.

I have at present under my care two cases of lupus carcinoma. In neither case had there been any radiological treatment prior to the onset of malignant disease. In both cases, although the disease is very advanced, there is no indication whatever of any enlargement of the lymphatic glands. Now this is exactly what might be expected if a carcinoma arises in a region where the lymph vascular system has been previously destroyed. On referring to the literature, with the kind assistance of the librarian of the Royal Society of Medicine, I found that in a collection of 122 cases Ashihara[2] found only 16 cases in which the glands were involved. In these 16 cases it may be assumed with great probability that either the disease had infiltrated into regions of intact lymphatics beyond the lupoid area or that the glands were tuberculous and not malignant. Here, then, is a striking fact which receives an easy and natural explanation upon the view that lupus is essentially a destructive lymphangitis. In one of the earlier editions of Sir John Bland-Sutton's book on "Tumours" there is a comment upon the failure of lupus carcinoma to disseminate. To Wild is attributed the explanation that dissemination is prevented by destruction of the lymphatic channels, but upon what evidence I do not know, since I have not found a reference to Wild's paper.

Schematic vertical section of the growing edge of an area of lupus. From above downwards the epidermis A, dermis BB, subcutaneous fat CC, deep fascia D, and muscle E are seen. The disease is spreading from left to right. At the right edge the normal lymphatic system of the skin is represented by dotted lines. *Just under the epidermis are the papillary end-sacs, uniting in the superficial dermis (plane of primary confluence) into small lymphatic vessels, which again unite to form vessels piercing the dermis and emptying into FFFF,* the fascial lymphatic plexus. At the left edge of the figure are two primary lupus nodules, each formed by the destruction of an arborisation of lymphatic vessels. The lymphangitis has spread along FF, the fascial lymphatic plexus towards the right, and has re-ascended the vessel HH to produce early infection of its arborisation KK. It is also beginning to ascend the remoter vessel L. In the deep fascial plexus it has spread beneath healthy skin to the point M. *The secondary confluence of the lymphatic vessels just deep to the skin is* omitted for the sake of simplicity.

MICROSCOPIC CHARACTERS OF THE GROWING EDGE.

The great labour which has been devoted to the histology of lupus has hitherto failed to explain why lupus is nodular, why it affects the superficial third of the dermis, why it apparently spreads discontinuously, and why the disease is so obstinately recurrent, although due to an avirulent form of the tubercle bacillus. The fact is that histologists have not based their investigations upon lymphatic anatomy, and have concentrated their attention upon the confused pictures of the later stages of the disease instead of studying the early changes seen at its microscopic growing edge. I must now describe three cases in which I investigated the microscopy of the growing edge of lupus beyond the visible area of disease.

CASE 1.—A patch of warty lupus at the base of the index finger. The most striking feature of the section is *the great papillary hypertrophy seen in its central diseased* portion. Measurement shows that at one end of the section in healthy skin the papillæ measure two units on the micro*meter scale. Passing across it they increase in length to* 10, 12, and, as a maximum, to 20 units of the scale. Then a decrease begins, and at the other edge of the section the *length averages only three units. At the edge* of the affected area, where there is no papillary hypertrophy, the first change noted is that the centre of each *papilla is occupied by a more or less solid column of* endothelial cells irregularly arranged. There is here no round-celled infiltration. From the central situation of these endothelial cell-columns it may be inferred with certainty that they are derived from the proliferation of the lining endothelium of a lymphatic vessel. We see, then, that an endo-lymphangitis is present in areas shortly to be invaded by the centrifugal spread of obvious lupus. In the superficial layers of the subjacent dermis *lines of similar endo*thelioid cells, often solid, but sometimes *presenting a central lumen, can be seen.* These lines show Y-shaped *junctions* and are arranged in a retiform manner. The appearances are just like those seen in an injected specimen of the skin lymphatics, and there can be no doubt that they represent an endolymphangitis of the dermal lymphatics, for their continuity *with the undoubted* central lymphatics of the papillæ can sometimes be traced.

Passing on, we note that the papillæ begin to show hypertrophy, *and that around the retiform columns of endothelial* cells collections of inflammatory round cells begin to appear. They form a definite band in the superficial layer of the dermis just like that seen in Paget's disease and in elephantiasis. This plane of the dermis is the plane of primary confluence of the lymphatic capillaries, and the concentration of the round-celled infiltration in this layer and in the papillæ is an additional proof that the disease is a lymphangitis. The round-celled infiltration appears to arise from the inability of the leucocytes brought by the blood-stream to pass away along the blocked lymphatics. In the deeper *dermis accompanying the blood-vessels are lines of round*celled infiltration and epithelioid cells. Since lymphatics are comitant to blood-vessels the nature of these appear*ances is clear. They represent lymphatics blocked by* lymphangitis and surrounded by round-cells which find their natural way of return cut off. We now reach a region of great papillary hypertrophy where the papillæ and the superficial third of the dermis are converted into granulation tissue containing giant cells. These giant cells tend to follow the line of the lymphatics in a very definite way. Sometimes a line of giant cells can be seen occupying the situation of a lymphatic in the centre of a papilla. At other times a vessel with proliferating endothelium but with a lumen still distinct can be seen to tail off into a line *of giant cells which follow the line of the original lymphatic.*

[2] Ueber das Lupus-Carcinom, by Dr. N. Ashihara (*Archiv für Dermatologie und Syphilis, 1901, p. 193*).

im as mentally defective. His attitude, demeanour, nd record are quite different from my idea of a oral imbecile. On the contrary, with the exception f this and one other act of stealing when he took ot money, but two articles he did not want and ever used, his conduct has been exemplary; it has een that of the boy who is almost too good, except hat at the present time he will not go to work. He may be suffering from incipient mental disease; in any case, we can only explain his conduct by studying his mental attitude. We have difficulty in classing him as mentally defective, because his intelligence is as good as that of large numbers of others of the same social class and education who are able to carry on quite well. We are, however, justified in regarding his limited intelligence as one factor in precipitating the present crisis. There must be other factors; those are to be found in the unconscious mind. This has not been thoroughly investigated, but help is gained by realising that he has a kind and indulgent mother, whose inclination is to shield her children in every possible way. The mother is not robust; the father is of similar temperament, with a record of serious ill-health, as he is a victim of consumption. He has struggled hard to bring up his family well, but is now breaking down under the strain; he has no longer a business of his own. We can easily imagine in such a home circle the growth and spread of a sense of inferiority and hopelessness of outlook; Providence seems to be against them. The boy himself is not strong, and when he feels a bit slack may have a suspicion that he will have just as bad luck as his father. The loving care that has shielded him has not promoted the development of grit. At the back of his unconscious mind may lurk the idea: "What's the good of my going to work? I can never hope to win through; at the best it is only postponing the evil day."

THE DELINQUENT'S SENSE OF INFERIORITY.

Developed in one way or another, the sense of inferiority is often found in the delinquent. The boy who cannot see the blackboard at school, and who does badly because his defect is not recognised and dealt with, feels he is inferior and cannot compete on equal terms with his fellows; let the temptation or the bad example come, and it is a short step to crime. Yet if you ask him why he did it, he cannot tell you either of his eye defect, or of the idea that comes welling up from the unconscious to influence his conduct. Often the sense of inferiority is developed because the child is awkward or slow, and then his stupid parents tell him that he will never be any good, and are always dinning into him that the only suitable head-dress for him is the dunce's cap. One of the most satisfactory cases I ever had was a man who went to the university rather late in life, because whenever as a boy he spoke of visions of a degree and a profession he was always told, "What's the good of your thinking of a university; you would never pass the entrance examination. far less get a degree." He was told he was so stupid he must go into business, a vocation which to my mind requires ability, and in which he failed because he had neither interest not aptitude.

These cases are closely allied to the so-called father or mother complex, where the authority exercised by one or both parents is so absolute that the child has no opportunity of developing his individuality and coming into his kingdom. Sometimes excessive authority develops the rebel type, that type who is openly hostile to all authority and looks upon rules and regulations as only made to be broken. Do not think I am advocating spoiling children; far from it, for a spoilt child has the worst chance of all in life. There must be firm and wise direction of the growing life. but the weight of authority must be steadily diminished till it reaches the vanishing point as the young person ends his teens. We must have discipline from without at first, but we want to develop later on internal discipline, mastery over self.

THE SEX COMPLEX: UNWISE ADULTS.

I must remind you that those who have to do with delinquents often find a sexual complex. Something of this sort is the explanation of many cases of stealing or other impulsive acts. Here again the mischief is in the environment, and in the home in particular. There has been no simple dealing with the problems of sex and development by the mother as the children begin to wonder and ask innocent questions. How can they help thinking of the wonderful mystery of life? Later on, instead of learning gradually, their ignorant minds are flooded with a mass of false teaching, imparted in the wrong way by bad companions. Teachers ought to know how much sexual irregularity there often is in and around a school. Wise supervision and a few frank words with the individual can do much good; but you can never put matters right by formal teaching in class. It is always an individual problem to be dealt with privately. Nor must you ever speak to the individual unless you feel you can help him.

I have dwelt rather long on environment; that is because, putting aside the limited number of cases of mental defect and of gross disease, the environment seems to me the most important matter. A short time ago I was told about a child of known bad parentage who was adopted by a good and kind couple; the girl went hopelessly wrong. It was suggested that this must be due to heredity. I should be glad to have particulars of similar cases, because one case proves nothing, but in such a case there is a possible fallacy. In the first place the girl was brought up as an only child, which is not desirable. Then I should like to know why the foster parents had no children of their own. Was there any fault on their part, or did nature realise that they were not suitable to be parents? A short time ago I saw an orphan delinquent girl whose case threw some light on this matter. When I asked her why she was so unhappy, she burst into tears and said, "Aunties are not mothers." The child must have discipline, but discipline in the early years at least must be tempered by love. This girl gave me an instance of the bad influence unwise guardians may have. On one occasion, when she was in a room alone with a boy cousin, her puritanical uncle came in, and finding them together, at once accused them of misconduct. This unjust accusation permanently estranged the boy from his father, and might have produced the situation the father wanted to prevent.

DISEASE.

A few words will suffice for the subject of disease, which, like mental defect, must always be considered in connexion with delinquency. As already suggested, eye and other defects may be very important; there must be a thorough physical examination, not only for definite disease, but also for slight disabilities, which may be the basis of a mental conflict. The constitutional diseases, especially tuberculous disease and syphilis, are not uncommon in criminals, and may partly explain their abnormal conduct. Both call for appropriate treatment. Syphilis may be inherited, but as we see it, it is more often acquired and therefore due to the environment, where we may blame either injudicious home training or abnormal social conditions. Tuberculous disease is due to both heredity and environment; there is the inherited predisposition, or rather lack of resistance, and later on the faulty hygiene. Epilepsy is extraordinarily important; it is the explanation of some criminal acts. but is often overlooked, especially when of a mild type or in the incipient stage. I know one boy, who had several severe fits when under my care, who was subsequently ordered to be birched by a bench of magistrates. Fortunately the sentence was not carried out, although its remission was not due to recognition of his disease.

CONCLUSION.

I can best sum up the problem of crime by quoting from Goring. "The crusade against crime may be large should be taken away in one piece with the area of skin excised. The test of the completeness of the removal is that muscular tissue should be seen in the floor of the resulting wound.

Excision.

Leloir, writing in 1891, condemned the excision of lupus, though he admitted that in certain exceptional cases excision followed by skin-grafting might be the only means of cure. English surgeons have not shared Leloir's dislike for the method. Thus Cheyne and Burghard (1903) consider that an early patch of lupus should be removed by an oval incision followed by suture. For such cases they consider the method ideal; in more extensive cases they advocate, wherever possible, excision followed by a plastic operation or by skin-grafting. The excision must be carried freely (at least a quarter of an inch) beyond the edge of the disease and well into the fat beneath, or it will not be successful. Dr. Arthur Whitfield—who, as dermatologist to King's College Hospital, no doubt had the opportunity of watching cases so operated upon—formed a high opinion of excision in early cases and found relapse "extremely rare." On the other hand, after excision of extensive lupus followed by skin-grafting, relapse occurred within the grafts in the great majority of cases. There is here a clear indication of the defects of the present method of excision. Although the plane of excision traverses the deep subcutaneous fat it leaves intact the subjacent infected lymphatic plexus of the deep fascia. The failure of excision conducted on these lines is an experimental proof of my contention that the deep fascial lymphatic plexus is the lurking place and the main channel of spread of the disease. This contention is not vitiated by the almost uniformly favourable results of the superficial excision of very early lupus, in which presumably either the deep fascial plexus is not yet infected, or the inflammatory reaction of the operation suffices to strangle fascial infection in an incipient stage.

Is it possible to devise a method of excision which shall accord with the conception of the disease as a capillary lymphangitis? The answer to this question will vary with the site and extent of the disease, but for certain cases, as on the limbs and trunk, it is in the affirmative. I have space only to describe the ideal method; I must leave it to you to judge of its limitations for any given case. In any operation those pathological facts must be taken into account of which I have offered proof: (1) That lupus is a destructive proliferative lymphangitis, only confined to the skin in its earliest stage. If the area affected exceeds half an inch in diameter it must be assumed for reasons of lymphatic anatomy that the subcutaneous tissue and the deep fascia are also infected. (2) That the disease is spreading in the deep fascia, not in the plane of the skin, and that accordingly the infected area of deep fascia is slightly larger than the infected area of skin. (3) That the visibly diseased area of skin is surrounded by a zone about a quarter of an inch wide in which microscopically tuberculous lymphangitis is already present.

Method of Operation.—The visibly infected skin must be circumscribed by a ring incision. In order to allow for the area of early microscopic infection, this incision must not come within a quarter of an inch of the visible edge of the disease. The skin edges must now be reflected back for a further quarter of an inch. The exposed area of deeper subcutaneous fat is then surrounded by a ring incision which marks out the area of deep fascia requiring removal. This area is raised from its edges towards its centre until the diseased deep fascia is removed. The surface of the muscles is exposed in the floor of the wound, which is sutured or skin-grafted.

Such an operation is obviously impracticable for extensive lupus of the face. In lupus of the limbs or trunk it should be the method of choice, unless the disease is very extensive. Superficial excisions, not including the deep fascia, are only allowable where removal of the latter layer is impossible on cosmetic or other grounds. They should always be supplemented by cauterising agents, which it may be hoped will excite sufficient reaction to destroy the foci of disease in the deep fascia. Skin-grafting should be deferred until the cauterised surface has produced healthy granulations. In such cases it may be doubted whether imperfect excision has any advantage over the older method of scraping combined with cauterisation. If the disease has spread to the trunk-lymphatics and the glands, the infected vessels and glands must be excised in one piece with the area of lupus (monobloc method of operation). A case which I described in the *British Journal of Surgery*[3] illustrates the successful application of this method. The patient remains well more than three years later.

Bier's Hyperæmia.

We have seen that a passive hyperæmia with increased transudation is normally present in lupus. It seems improbable that the artificial exaggeration of this characteristic feature of the disease should exert a curative effect. It might, indeed, be argued that the repair seen in the older central area of a patch of lupus is due to hyperæmia. But the presence of hypertrophied papillæ beyond the visible edge of the disease makes it probable that slight venous obstruction is present in the earliest stage of infection and obviously it does not interfere with the evolution of the disease. The conclusion seems justified that artificial passive hyperæmia is most unlikely to arrest the spread of lupus, and it is worthy of note that Bier has ceased to employ this method. He states: "With congestion hyperæmia by bandage I have seen no results or only transitory improvement of ulcerative lupus of the extremities."

Finsen Light Treatment.

Since sunlight is a notorious enemy of tubercle it is not surprising that the Finsen arc lamp, which supplies light rays deprived of their heat, has a curative effect on the cutaneous manifestations of lupus. It is instructive to note that the method is ineffective unless the surface acted upon is blanched and made transparent by the pressure of a quartz disc. Even when this is done the light rays can only be expected to penetrate to the superficial layers of the dermis. In other words, the action is a surface action. The superficial nodules disappear, leaving a good scar, but the results obtained are rarely permanent, though the treatment is prolonged, tedious, and expensive. If, as I have tried to prove, lupus is a capillary lymphangitis affecting the lymphatics of the subcutaneous tissue and the deep fascia as well as those of the skin, the failure of the Finsen light method to fulfil its early promise is easy to understand, for it cannot reach the deep fascia. It should be abandoned for methods more rational and effective.

Radium Treatment.

In the report of the Radium Institute for 1919, Dr. Hayward Pinch states regarding lupus vulgaris: "Cases of long standing which have proved non-amenable to Finsen light X rays, CO_2, snow, scarification, caustics, &c., are sometimes quickly and effectively cured by radium, and the treatment is well worthy of a trial when other methods have failed." It is advised that ulcerated areas should receive an unscreened exposure of one and a half hours, while indurated and non-ulcerative areas are best treated with long screened exposures. The screen should be 1 mm. silver or 2 mm. lead. It seems probable that the future will see an extension of radium therapy in lupus as the method of choice. Apart from its direct action on the tuberculous tissue, radium is known to have the power of exciting an aseptic lymphangitis, and in this way by obliterating the normal lymphatic vessels around the infected area it can probably stop the progress of the disease by an insuperable barrier. To those radiologists interested in the surface application of radium, I would suggest, as the best means of erecting such a barrier, an encirclement policy working from the sound tissues towards the diseased area. It must be recognised, too, that the layer to be effectively irradiated is the material, I have found the syndrome much more frequently incomplete (amongst cases at Harrogate).

---

[3] Brit. Jour. of Surg., January, 1920.

Nearly thirty years ago, at the Bath Mineral Water Hospital, I was taught the diagnostic significance of the temporo-maxillary joint in rheumatoid arthritis, using that much abused term, not as synonymous with, but as absolutely distinctive from, osteo-arthritis. The accompanying neck symptom in this complaint was also noted. Further experience showed the syndrome to be practically invariable in poly-articular gonorrhœal arthritis. Then, as the importance of buccal and other infections became appreciated, the same rule was found to hold good; and later, in a veritable epidemic of post-dysenteric arthritis, consequent on the Gallipoli campaign, the syndrome was again unfailing. In 11 cases of arthritis occurring during or immediately after the acute specific fevers, the jaw and neck were always affected; and finally I found it in two cases which appeared to be caused by, or at any rate exacerbated by, some toxic action of the thyroid.

Two Main Divisions of Polyarthritis.

Not in a single instance could I discover it in a case of rheumatism or gout in which other infection could be excluded. Thus gradually but irresistibly the conclusion was arrived at that polyarthritic cases could be divided into two main groups, the jaw-neck syndrome cases, that were never gouty or rheumatic, but were always due to a definite infection or toxin, and might be classed broadly as the infective or toxic group, and the non-syndrome cases, that were due to gout, rheumatism, or traumatism.

It is true that acute rheumatism is also almost certainly due to an infection, so that it is perhaps hardly logical to call one the infective and the other the non-infective group, and a more precise term is certainly desirable for the gouty and rheumatic group; indeed, were it not for the fear of rendering the confusion of names worse confounded, I would suggest calling one the "rheumatic" group, and the other—the syndrome series—the "rheumatoid" group, for the latter name commits us to no theory. Whatever the nomenclature, however, the division is practically convenient, more especially from the point of view of treatment.

The Term "Rheumatism."

At present we are confronted with the fact that the word rheumatism is used in conjunction with such an adjective as gonorrhœal. It has always been the bane of discussion on the "rheumatic" diseases that there has been no accepted definition of the meaning of the term rheumatism, and further, that in speaking of the different members of the so-called rheumatic group different authorities have used the same term to signify different conditions; I refer especially to the use of the words "rheumatoid arthritis." This had led to a hopeless confusion of issues, and I would enter a plea for a fundamental clearing of our nomenclature, so that we may know exactly what we are talking about. Before venturing to suggest a comprehensive classification, therefore, I propose to submit a definition of the terms employed. The term "rheumatic" is so useful and so universal that we can hardly forgo it, indeed, there is no other adjective to fill its indispensable place; at the same time it is so vague, and used in such varying senses, as to be extremely misleading. This, perhaps, is due to the gradual evolution of our ideas from a humoral pathology, through a chemical and neural phase, to a bacteriological view, and at the back of our minds is there not still a hazy subconscious blending of these various outlooks? While invasion by micro-organisms is generally conceded as a cause of many of the "rheumatic" conditions, there is, as has been already mentioned, evidence that the influence of internal secretions may in some cases possibly prove a factor in the problem; and so the wheel goes round full circle to meet the old humoral point.

If we must use the word "rheumatic," and there seems at present no help for it, and if we are not going to confine it strictly to rheumatic fever, I would define it in its loose generic sense to cover all forms of arthritis that do not tend habitually to suppuration. Thus pneumococcal and syphilitic arthritis, for instance, would be excluded, for the former tends very frequently to suppuration,[3] [4] and the latter, though sometimes classed amongst the rheumatisms, would appear, in untreated cases,[5] very frequently to do the same, and it is only because we so seldom meet with absolutely untreated syphilis that we see the milder forms of arthritis. Probably it will be found that such a division would include nearly all cases of toxic arthritis and a minority of cases of actual joint invasion.

Again, the term might be stretched to cover the symptoms habitually associated with such arthritis, such as fibrositis and certain forms of neuritis and iritis. Further, to include the test of reaction to salicylates or to weather is hopeless, for nearly all pains react to weather and to acetyl-salicylic acid. Used in this loose form "rheumatism" is a useful word, whose place cannot be filled by the substitution of "arthritis," which, in names like gonorrhœal arthritis, does not by any means cover the whole ground. If, as well may be, such a use of the word rheumatism is objected to, a new and universally accepted term must be invented.

Definition of Terms.

The diseases usually considered as belonging to the "rheumatic" group are: gout, acute and chronic; rheumatism, acute and chronic, rheumatoid arthritis, including Still's disease[6]; gonorrhœal arthritis; various forms of infective and toxic arthritis; osteo-arthritis, including spondylitis deformans; and certain forms of neuritis, iritis, and affections of the skin. In addition, there are certain borderland and disputable conditions, such as chorea and erythema nodosum, which, as we are only concerned with the classification of *arthritis* by means of the syndrome, can be dismissed from present consideration.

Group A.

1. *Gout.*—Acute or chronic is an entity of which we hold, or think we hold, a fairly clear conception, and it needs no definition here.

2. *Acute rheumatism* or *rheumatic fever*, whether or no we agree as to its causation by the diplococcus of Poynton and Paine, is equally clearly-cut in our minds. *Chronic rheumatism*, if we admit the unofficial term, means (it is to be supposed) recurrent subacute attacks of arthritis or fibrositis in a person who has had rheumatic fever, or at least has a strong family history of it, and whose symptoms are not due to some other infection. These constitute the non-syndrome group.

Group B.

In this group the usual cause of the arthritis appears to be a toxin, though in some cases there may be an actual invasion of the joints by micro-organisms. The group as a whole is distinguished from Group A by the almost invariable presence of the jaw-neck syndrome. In rare cases the syndrome may be incomplete, especially as regards the jaw symptom.

3. *Gonorrhœal "rheumatism."*—This condition is interesting as, while it is a well-defined and well-recognised entity, it constitutes a prototype of the whole ensuing group. The disease may be a toxic arthritis, or the joints may be directly infected and show the gonococcus in pure culture, or again there may be a secondary infection with other organisms (cf. infra, Influenza).

The clinical picture is too familiar for comment, but I would draw attention to the following points: The jaw-neck syndrome is nearly always present at some stage of the disease; there is frequently, especially in the acute stages, a characteristic careworn facies; and there is sometimes a bony spur from the os calcis into the plantar fascia, which makes a striking X ray picture. Atrophic bone changes in the phalanges, as in rheumatoid arthritis, have been described but must certainly be comparatively rare. There is, however, frequently seen in a skiagram a curious appearance of obliteration of the interphalangal joint-space, suggesting a non-existent ankylosis. This is due presumably to atrophy of the articular cartilages, and, while by no means pathognomonic, is very suggestive of gonorrhœal infection. There is apt to be a good deal of constitutional disturbance, with a tendency to anæmia and debility. The joints are not much benefited by sodium salicylate, though they may be relieved

Heredity, then, seldom explains delinquency, though bad heredity is often associated with it, because we can accept Goring's statement that the criminal is an inferior man; and such inferiority, whether of intelligence, physique, or what not, tends to be inherited. But if we study all the facts of a criminal family, we often find that an irregular family life, a lack of proper training or a definite training in wrong-doing, a faulty attitude to life and society, play a more important part. At one end of the scale we may have the hereditary criminal; at the other the delinquent, whose fate is entirely due to bad companions. I have never seen either of the extreme cases, but I have seen many intermediate ones containing an element of both, the causation usually being highly complex. Dr. Healy, after examining nearly three thousand delinquents, prepared a table which showed that only in one-sixth was heredity a factor, and even then it was only a minor factor.[2] As Dr. Healy says, the facts must be carefully sifted—e.g., a woman may be a prostitute, and the daughter of a prostitute, but both she and her mother may be the victims of environment.

When speaking of heredity we must recognise there is a psychical inheritance as well as a physical. The child may inherit the tendency to evade, rather than face difficulties; if the parents do not deal with their mental conflicts it is harder still for the children to face reality; but usually such weakness "acts like an infection rather than a transmission."[3]

ENVIRONMENT.

Delinquency must really be the result of all the numerous factors in the make-up and environment of an individual; it is not due to a special biological organisation. Dr. Healy[4] says "there are a few well-differentiated classes, such as the definitely feeble-minded, or the insane, or the senile dements, who readily commit crime." But "human beings have many-sided natures, and the variabilities in the proportion of this or that characteristic are immense." There is, therefore, "no fitting into single pigeonholes." Environment, therefore, is of great importance, especially if we give it a wide interpretation. Social conditions have much influence; faulty hygiene tends to the development of the inferior man, and so predisposes to delinquency. No scheme for dealing with crime is complete that does not include social betterment. Healthy exercise and recreation must be possible for all. Training is important, especially that received at home during the earliest years of life. My experience of the habitual criminal is that he generally goes wrong very early. The so-called first offender is seldom really a first offender; it is his first appearance before the court, but some form of delinquency has usually been going on for years. Goring, when discussing habitual criminals, said that "the nodal, or commonest age, for recruiting, is between 15 and 20";[5] but then Goring only ascertained the age, at their first conviction, of convicts. Those of us who have had the opportunity of examining cases in the children's courts, and studying abnormal conduct in the young, know that the critical period must be placed much earlier. Nearly all the young delinquents I have examined were on the wrong path at 10 years of age, and often earlier than that. The first offence is not necessarily of the same kind as the first conviction; for instance, stealing is often preceded by lying, in consequence of which the offender gradually gets a false conception of reality, if indeed he ever had a true one. It would be to the public advantage if more magistrates realised that the so-called first offender is not usually an innocent little person to be dismissed with a caution, but an individual on the wrong lines whose case requires thorough expert examination.

This leads me on to our modern conceptions of the springs of conduct and of the term environment. Take environment first, for that is the simpler of the two. It means not only the house and street in which the individual lives, but also the climate, opportunities for play, exercise, and so on; it means not only the persons in the home, but their attitude to life, the way they meet its difficulties; it includes also all the experiences of life, in short, the whole content of the mind, including the emotions, instincts, and ideals. The psychic environment, developed and fostered by the conduct and attitude of the home circle, is the most important. This environment exists in the mind and is carried everywhere with him by the individual. It requires investigation in most cases of abnormal conduct. Dr. Healy says that if we want to determine the causal factors in delinquency the prime consideration is the mental life of the individual. "Not only is this shown by the undue proportion of feeblemindedness, epilepsy, and insanity among delinquents, but also by the mental disappointments, irritations, and conflicts which very frequently are at the roots of offending careers."[6]

How are we to study the mental life of the individual? The mind is very difficult to explore. In recent years we have accepted and extended the conception of the mind as consisting of two parts, the conscious and the unconscious. The content of the conscious mind is small and limited; the unconscious mind is bigger and more comprehensive. The whole mind has been compared to an iceberg of which the part above the water is only a small fraction of the whole; the visible portion corresponds to the conscious mind, the larger and unseen to the unconscious. In some cases of criminality the explanation is simple, because the motive is in the conscious mind, a region comparatively easily investigated; but in many cases the springs of conduct are hidden in the unconscious, and absolutely unknown to the individual himself. We may have a shrewd suspicion as to what some of them are, but we cannot be certain till he recognises them too. It is the unconscious motive which explains those criminal acts in which the culprit gains nothing, or at any rate makes no use of what he does gain. Such a delinquent will often say, truthfully, that he had an irresistible impulse and cannot understand why he did it.

AN ILLUSTRATIVE CASE.

I will give you an example, selected because it is connected with the problem of the so-called moral imbecile. A youth of 18, of previous exemplary conduct, when out in the street after dark, felt an irresistible impulse to break into a house he was passing. He opened a window, got in, and picked up a few shillings he found lying on the table. He then walked to the front door, unlocked it, took out the key, and having locked the door on the outside, put the key in his pocket. He went home to bed. He did not require the money, having as much as he wanted at the time. Next morning he felt upset and sorry for the unfortunate people who were locked in their house. Accordingly he went back and dropped the key in the letter-box. A woman ran out after him, and said he must be the person who had broken into the house and taken the money; he admitted that he was. When this young man is examined we find that he is not highly intelligent, as he has a mental age of only 13. With such a mental age, however, it would be very difficult, if indeed possible, to certify him under the Mental Deficiency Act, especially as he has a good school record and got into the highest standard. The suggestion then comes that as he is somewhat unintelligent and has committed criminal acts he must be a moral imbecile, and should be treated as such. I consider that here such a course is far less justifiable than certifying the syndrome test we can at once class our patient under group A or B, a classification that helps us to find the cause. In class A, the diagnosis lies between true gout and true rheumatism, and is, therefore, as a rule, comparatively easy, and the treatment is more or less specific. In class B the diagnosis will lie, in nine cases out of ten, between gonorrhœal, rheumatoid, and toxic arthritis; if it is the latter, we may perhaps be able to remove the cause—be it a tooth, an appendix, or an infected gall-bladder—without wasting time in attempting to relieve symptoms. But gonorrhœa as the primary cause is exceedingly common. To this infection I believed I was able to trace 10 per cent. of all my "rheumatic" cases admitted to the Mineral Water Hospital at Rotorua.

[6] Healy: Op. cit., p. 163.

The diagnosis of rheumatoid disease is unfortunately generally easier than the treatment, but it is a fairly safe rule that all affections coming under class B require a *tonic* line of treatment, or in other words, that the resistance of the patient to micro-organisms and toxins must be increased. The whole group would appear to offer a peculiarly appropriate field for the use of vaccines, success in the use of which will depend so largely on accuracy in diagnosis.

In classes C and D we can sometimes remove the cause, and sometimes mitigate the symptoms, but, as a general rule, once osteo-arthritis had developed, even removal of the cause will be but a palliative, for it is removed too late, and the mischief already done is permanent. In this condition we may lessen the disability and increase the range of movement by mechanical means, and we may relieve pain, but very often our chief efforts should be concentrated on muscle rather than on bone, on the recuperation of important and essential muscles showing trophic wasting as a consequence of the arthritis.

Suggested Classification of the "Rheumatic" Group of Arthritic Diseases.

A.—Jaw-neck syndrome absent.	1. Gout.	Acute. Chronic.	Ending all in D. 10. Osteo-arthritis.
	2. Rheumatism.	Acute. Chronic.	
B.—Jaw-neck syndrome present. The toxic and infective group.	3. Gonorrhœal. 4. Dysenteric. 5. Toxic. 6. Rheumatoid.	Arthritis or rheumatism.	
	7. Arthritis following acute specific fevers—e.g., Measles, Scarlet fever, Enteric, Mumps, Influenza.		
	8. Thyroid arthritis or rheumatism.		
	9. Traumatic arthritis.		
C.—Not rheumatic.

BRISTOL MATERNITY HOSPITAL.—On Nov. 11th a hospital of 18 beds for the reception of maternity cases was formally opened by Dr. Janet Campbell. The premises, which have been used for this purpose since February, were purchased from the committee of the Homœopathic Hospital, which has removed its work to larger premises in another part of Bristol. The patients' fees cover about half the annual expense, the remainder being found by voluntary contribution and Government subsidy. In her speech Dr. Campbell said that the Ministry of Health was in favour of the establishment of a number of small maternity homes rather than of one large hospital.

A METHOD FOR DIMINISHING MORTALITY IN EMPYEMA

IN INFANCY AND CHILDHOOD.

BY F. JOHN POYNTON, M.D., F.R.C.P. LOND.,
PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL AND HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET;

AND

F. N. REYNOLDS, M.R.C.S., L.R.C.P. LOND.,
RESIDENT MEDICAL SUPERINTENDENT, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

EMPYEMA is recognised as a serious and comparatively frequent event in childhood, and on this account we believe that the results of this investigation into its occurrence in infancy—that is, in the first two years of life—may be of general interest. As will be apparent, the mortality at this early age is high, and we venture to hope that the method employed by us, of which a detailed description, with illustrations, is given below, may be as helpful to others as it has been to us in diminishing that mortality. This method is not new in principle, as the literature clearly shows. In fact, the surgical principle is in itself as clear as daylight, and is maintained when the septic fluid is safely and completely withdrawn from the chest without recurrence. As a step forward in this direction the method has proved of practical service to us in dealing with children of all ages.

Present Position of the Subject.

Before we enter upon the analysis of the cases in infants, which we have collected, a short review of the present position of the subject of the treatment of empyema will assist us in presenting the particular points we desire to emphasise. Empyema is recognised as one of the most treacherous and puzzling conditions in pulmonary disease. Some cases are simple and straightforward, but others are almost beyond diagnosis, even with radiological assistance, and empyema must be classified with typhoid fever and with tuberculous meningitis as one of those conditions which may humble the most confident diagnostician. The difficulties, as this analysis shows, are many and diverse, and depend in part on the nature, but still more upon the virulence, of the infection. They also depend upon the age and strength of the child, the regional anatomy of the abscess, and the duration of its existence. Post-mortem studies explain how it is that some empyemata are easy to deal with, some difficult, and some almost impossible. So much is common knowledge, but the question is whether in infants, and still more in older children, we can get rid of the abscess by any method safer and no less satisfactory than the usual incision. resection of a piece of rib, and drainage. Hard things have been said of drainage-tubes in treatment, but a physician will tell a surgeon that if there is one thing likely to cause suffering and harm to a child it is the premature removal of a drainage-tube; and this fact has bearing on the whole surgical aspect of the subject. The slipping of these tubes into the pleura, though unfortunately not an impossible occurrence, does not enter into the present problem; for our purpose it may be classed under "regrettable incidents." Let us suppose, however, that the pleura is opened without resection, drained, cleansed, and closed at once. If the case is a favourable one, the result is excellent, but if some pus is left behind, or the infection is still active, more pus is formed and the position becomes difficult. Children cannot be operated upon with impunity, and it is hard to decide when and where to explore again, and adhesions, too, may lead to trouble. Except that the wound is not open, the position is then closely akin to premature removal of the drainage-tube. It is not to be supposed that use of the drainage-tube is ideal or cannot be improved upon, but our analysis does not support any reason for a fierce conducted in three directions. The effort may be made to modify inherited tendency by appropriate educational measures; or else to modify opportunity for crime by segregation and supervision of the unfit; or else—and this is attacking the evil at its very root—to regulate the reproduction of those degrees of constitutional qualities—feeblemindedness, inebriety, epilepsy, deficient social instinct, &c.—which conduce to the committing of crime."[7] Goring then went on to say that we must have facts, and suggested that the results he had obtained might serve as a stimulus to a more extended inquiry, including the homes and haunts of the offenders. We must go beyond this; the inquiry most necessary now is into the mental life of the delinquent, on the lines on which Dr. Healy is working in America.

In conclusion, I would refer briefly to the *Birmingham scheme for special medical examination* of mental defectives and other persons of unstable mentality brought before the courts. This scheme was inaugurated because it was realised that in spite of the working of the Mental Deficiency Act, 1913, there were still mental defectives coming before the courts, and in some cases actually being sent to prison. What was intended in the first place chiefly for the benefit of mental defectives should have far-reaching consequences for the benefit of the more normal. It has given those of us who are concerned in the work the opportunity of showing that in addition to mental defectives there are a large number of other persons who ought not to be looked upon as fully responsible, because there is some psychic abnormality resulting from an environment over which they had no control.

THE JAW-NECK SYNDROME:
ITS SIGNIFICANCE IN THE RHEUMATIC GROUP OF DISEASES.

BY ARTHUR STANLEY HERBERT, O.B.E., M.D., B.S. LOND.,
LATE GOVERNMENT BALNEOLOGIST TO THE DOMINION OF NEW ZEALAND.

WHILE it is well-known that involvement of the temporo-maxillary joint is common in certain forms of arthritis and uncommon in others, the paramount importance of this point as a differentiating symptom in the diagnosis, and consequently in the treatment, of the so-called rheumatic diseases is not, I believe, sufficiently widely recognised. The whole heterogeneous medley of diseases generally and vaguely classed under the heading of "rheumatic" or gouty can be divided sharply into two groups, those in which the temporo-maxillary joint is involved, and those in which it is not.

Temporo-Maxillary Joint and Conditions due to Bacterial Toxins.

The importance of the division lies in the fact that if in any case of arthritis we find this joint affected, we can at once conclude that we are dealing with a condition due to some bacterial toxin, and can say definitely, confidently, and finally that it is *not* one of gout, however closely that disease may be simulated. Could we with any certainty define our conception of rheumatism and limit the application of the term to cover only rheumatic fever and those subacute and chronic cases which are its sequelæ or appear to be caused solely by climatic conditions, I would extend the axiom, and say that we can definitely exclude both gout and rheumatism. For while acute rheumatism is generally conceded to be due to microbic invasion, yet the toxin does not appear to select this particular joint.

A rheumatic or gouty person may, of course, have his jaws affected, for he is no more and no less immune than other people from the various toxins which affect the joints, but the jaw lesion is due to some secondary or superadded infection, and we may seek the underlying cause in gonorrhœa, rheumatoid arthritis, dysentery, oral sepsis, or in some other form of infective or toxic agency. One other and confirmatory symptom shares in this pathognomonic import—namely, pain, stiffness, and sometimes grating in the back of the neck just below the occiput. The cause of this pain is, perhaps, a little obscure, for the X ray appearances are variable, and post-mortem evidence in these cases is difficult to obtain. There would generally seem to be an arthritis more especially of the occipito-atlantoid or upper cervical intervertebral joints, but sometimes the symptoms seem to be caused rather by involvement of the spinous processes and of the periosteal and fibrous tissues in connexion with them, for in advanced cases there is often bony thickening of the cervical spines, with much fibrous matting about the back of the neck, while there may be no pain on vertical pressure, although this is, of course, inconclusive evidence.

Some light is thrown on the pathology of the condition by the experiments of Nathan,[1] who produced a polyarthritis in dogs by inoculation with streptococci, and showed that the vertebral changes were similar to those induced in the skeleton elsewhere—viz., endosteal and sub-periosteal inflammation, with a sterile intra-, peri-, and para-articular exudation. In the spine this exudate involved the epidural space and the vertebral notches, and caused root or spinal irritation or compression. This symptom is not met with in pure rheumatism or gout, it is nearly always coincident with the jaw symptom, and like it, is always a sign of some other form of arthritis.

Meaning of the Syndrome.

The syndrome has been spoken of as pathognomonic of rheumatoid arthritis. This, however, is only a half-truth. While it certainly is present in nearly every case of rheumatoid arthritis, it is pathognomonic, not of that disease, but of a whole group of infective and toxic diseases of which rheumatoid arthritis is but a member and a type. Garrod[2] maintained the diagnostic value of the jaw-neck syndrome in rheumatoid arthritis, pointing out its absence in gout and acute rheumatism and its "occasional" presence in gonorrhœal rheumatism, and several writers of monographs on rheumatoid arthritis have been equally emphatic, but the text-books on medicine as a rule, although they stress the involvement of the jaws in rheumatoid arthritis and mention that arthritis of the spine is common in this complaint, do not sufficiently emphasise the localised cervical arthritis; nor does any authority so far as I am aware hint at the broader significance of the syndrome as a sign pathognomonic of one great group of infective arthritic diseases.

I would put it as a definite law that in gout and true rheumatism the syndrome is always absent, and conversely, that in the toxic and infective group it is practically always present.

It must be admitted that the above statements may appear somewhat dogmatic and sweeping; there may be, indeed there must be, exceptions to this as to every other hard-and-fast convenient rule, but I think the exceptions are not numerous. Thus, while the syndrome is never present in gout, and I believe never in rheumatism, it is occasionally absent in the toxic group, and more especially it may be incomplete, the jaw symptom being the sign generally lacking. Again, the syndrome may be absent more frequently in some countries and climates than in others, a phenomenon quite explicable, for we know that variations in the strains of micro-organisms occur under such conditions.

Thus the rule was formulated from a careful analysis, extending over a period of 17 years, of a very large number of arthritic cases seen in hospital and private practice while I was in charge of the Government Baths and Sanatorium at Rotorua, New Zealand, and the exceptions to it appeared negligible. Yet, on my return to England, and with much less clinical

(B) *Method of procedure.*—After a preliminary exploratory puncture the site of operation, which will be referred to later, is anæsthetised with novocaine.

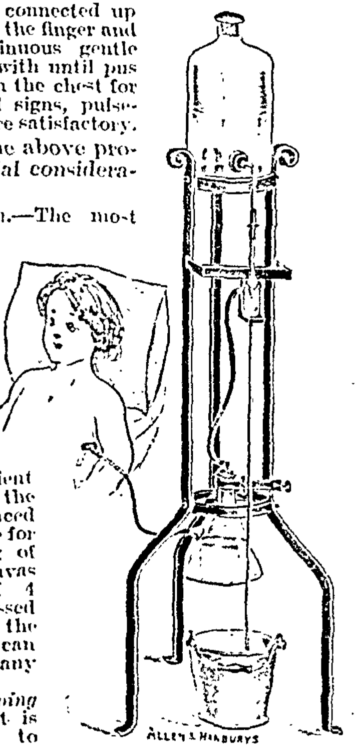
Tapes having been threaded through the shield of the cannula, the latter is introduced into the pleural cavity by means of the trocar, and the tapes are tied securely round the chest wall. The rubber tube is held by the open end, and the metal rod is passed down and pressed against the closed end until the tube is stretched sufficiently to allow it to pass easily through the cannula. The trocar is now withdrawn and a finger, wrapped in gauze, instantly placed over the opening. The tube is taken, stretched on the introducer, and carefully slipped under the finger and through the cannula, being introduced as far as may be thought necessary according to the size of the patient and extent of the empyema (the actual distance, in any particular case, can be ascertained by having marks on the tube at intervals of 1 inch). (Fig. 2.) The introducer is gradually withdrawn and the tube tightly pinched between finger and thumb close to the chest wall. The free end of the tube is connected up with White's pump, and the finger and thumb removed. Continuous gentle aspiration is persisted with until pus has ceased to come from the chest for 48 hours, and physical signs, pulse-rate, and temperature are satisfactory.

Certain points in the above procedure demand special consideration:—

1. *Site of operation.*—The most comfortable place for the patient, and at the same time the easiest for after-treatment, is a rib space as low as possible just anterior to the mid-axillary line. In this position the patient can lie on the affected side without interfering with the tube. If it is necessary or convenient to drain from behind, the patient can easily be placed against a bed-rest, made for the purpose, consisting of a wooden frame with canvas strips at intervals of 4 inches. The tube is passed through a space in the frame, and the patient can then be placed in any required position.

2. *Fixing and keeping cannula in position.*—It is advisable, in addition to the tapes, to place straps of adhesive plaster over and at right angles to the shield on either side of the cannula. A gauze dressing and a firm figure-of-8 bandage are then applied.

FIG. 2.



Showing the cannula in position and the tube connected up with White's pump.

3. *Escape of pus.*—In passing the rubber tube through the cannula, care must be taken to avoid any escape of pus whereby the puncture wound may become infected.

(C) *Advantages of the method.*—1. The period of illness is shortened. In cases treated by rib resection the average time before the wound is healed is six weeks; with the method described above the average time between insertion of the cannula and complete healing has been 15 days—a figure which would be much lower but for Case 3 (quoted below) which required four weeks. The explanation of this advantage is that: 2. There is no secondary infection of the pleural cavity. The rubber tube has a larger lumen than the cannula, so that, when released from the introducer, it expands and fits the cannula tightly, preventing any leakage of pus, soiling of the wound, and re-infection backwards to the pleural cavity. Another important point in the shortening of the illness is that osteomyelitis of the rib, so common after resection, does not occur. 3. No anæsthetic is required. The whole procedure can be carried out in a few minutes, causing very little disturbance and without removing the patient from bed; thus eliminating all the risks attendant upon moving a seriously ill child to the theatre and giving an anæsthetic. 4. Surgical trauma and its consequent shock are reduced to a minimum. The pain and discomfort of inserting the trocar are no more serious than exploration with a needle. 5. No daily dressing is required. Those who have seen what mental and physical suffering so many children endure for weeks after resection of rib will readily appreciate what a relief this method will be to all concerned. 6. The patient can assume any required position without fear that drainage will be interfered with. 7. The drainage is continuous and complete. Pus cannot collect in the bottom of the cavity and depend upon the position of the patient or upon expiratory efforts for its expulsion. 8. Expansion of the lung is assisted. The suction produces a negative pressure of 8 mm.Hg; this being more than the normal negative pressure of the pleural cavity, the lung tends to expand and assume its normal function more readily. 9. The removal of the pus is gradual. The continuous suction causes a steady slow outflow of pus, and it is some hours before the cavity is emptied; a displaced heart is thereby allowed to reassume its normal position quietly and gradually without the suddenness which is bound to occur if incision and drainage are employed. This fact is important when one recalls cases of syncope due to sudden withdrawal of pus and the replacement of a displaced heart.

(D) *Practical difficulties.*—1. Occasional blockage of the tube by masses of fibrinous lymph. It is remarkable how much solid matter will be sucked through, but should blockage occur, it can be remedied by increasing the suction by stretching the tube out between the fingers and expressing its contents into the flask by an action which may be compared with "milking." If this fails the plug of lymph can be washed away by injecting a few cubic centimetres of sterile saline into the tube. This difficulty has, in our opinion, been somewhat exaggerated by previous writers, for in none of our series of ten cases has there been failure to drain the chest by this method. 2. It is obvious that, as has been pointed out in the earlier part of this paper, there will be chronic or unusual cases in which this method will not be suitable.

(E) *Illustrative cases.*—Cases in which we have used this method, all of which recovered, varied in age between 15 months and 11 years. Among these were three under 2 years of age, which, therefore, come within the scope of this paper. The first and second of these show how simple and successful this method may be, while in the third we believe life would have been lost had incision and drainage, with or without resection, been undertaken.

CASE 1.—Fred G., aged 18 months. Admitted to the Children's Hospital, Great Ormond-street, on Jan. 12th, 1921, with an empyema at the right base following broncho-pneumonia. He was a pale wasted infant in very bad general condition. Exploratory puncture confirmed the presence of pneumococcal pus. The chest was drained by the method described for five days, and the child made an uninterrupted recovery.

CASE 2.—Louie B., aged 18 months. Admitted to hospital, May 7th, 1921, with broncho-pneumonia; seven days later empyema developed at the left base. The chest was drained for eight days by aspiration, and two weeks later the child was discharged, quite well.

CASE 3.—Lilian B. aged 18 months. Admitted to hospital, June 7th, 1921, with a large empyema on the left side. The heart was displaced to ½ inch outside the right nipple line. Patient was very ill, with a pulse-rate of over 160, respirations 80 per minute, temperature 100° F., and much cyanosis and dyspnœa. Drainage was commenced and proceeded satisfactorily. Ten days later the lung was expanding well, but there was a copious amount of pus still being aspirated. Unfortunately the tube was twice dislodged accidentally, and there was infection of the soft tissues round the cannula. Four weeks after admission, however, complete healing had taken place. Any serious operative treatment on admission would have been attended with very grave risk. The child made a good recovery, with the affected lung working well.

by aspirin. In view of the not infrequent secondary infections, it is important to remember that the condition may be waked by some other infection 20 years after a wholly forgotten and insignificant gonorrhœa followed by an equally mild and ignored " rheumatism."

4. *Post-dysenteric Arthritis or Rheumatism.*—The clinical picture is identical with that of the gonorrhœal variety except that there never appears to be a spur from the os calcis. This may be due, of course, to the relatively smaller number of patients that one sees. I examined, however, 50 cases for this condition with negative results.

5. *Toxic Arthritis or Rheumatism.*—In this condition the joint trouble is set up by the toxin evolved from an infected focus, and there is no invasion of the joints by micro-organisms. The toxin may act as a direct poison on the joint, or it is possible may act via the central nervous system; indeed, it is strongly held by some authorities that rheumatoid arthritis is a tropho-neurosis of this nature. Further, I would suggest that the toxin may act sometimes through the endocrine glands. (Vide infra, Thyroid.) The site of infection may be localised, as in the tonsil, a tooth, the nose, the ear, the gall-bladder, or the appendix, or there may be auto-intoxication from the bowel. The infecting organisms, and consequently the toxins, may be of varied nature, but the pathological changes in the joints, though they may vary thereby in intensity, do not vary in kind with the infection. The condition is sometimes wholly indistinguishable from rheumatoid arthritis, but as a rule the clinical picture is less complete, the arthritis less typical and severe, and there is less trophic disturbance of the bones and skin. Provided that no secondary nidus of infection has developed, it tends to clear up when the original cause—e.g., oral or nasal sepsis—is removed. In this respect it differs from those infective cases—e.g., some gonorrhœal ones—in which there is actual invasion of the joints by micro-organisms. According to Goldthwait,[7] however, the coexistence of toxic and infected joints may occur in the same individual.

6. *Rheumatoid Arthritis.*—This disease, possibly caused by a specific infection, is sometimes wholly indistinguishable from other members of the infective group. Whether it is a definite entity or whether it is merely a member of the group, a form of toxic arthritis caused by varying infections, is still a matter of dispute. The completeness of the clinical picture leads me personally to consider it a specific disease. Like the rest of the group, of course, it shows the jaw-neck syndrome, but is distinguished generally by the more pronounced symmetry of the articular and periarticular lesions, as evidenced especially in the first interphalangeal joints of the ring and middle fingers; by the more marked trophic changes of the bones, as evidenced in the X ray picture by the rarefaction of the phalanges in the neighbourhood of affected joints; by neurotrophic phenomena, such as sweating palms and bronzed skin; by persistent tachycardia; and by its predilection for women.

7. *Arthritis following the Acute Specific Fevers.*—Clinically these cases are quite indistinguishable from other members of the group. Except in its origin, there is nothing whatever to differentiate a case of post-measles arthritis from a post-dysenteric case, and I have seen during an epidemic of influenza an attack of that disease light up an old gonorrhœal arthritis. In recent years I have seen toxic arthritis consequent on measles, scarlet fever, enteric, mumps, and influenza—11 cases in all, and in each case there was observable the jaw-neck syndrome.

8. *Thyroid Arthritis.*—The name is introduced in all diffidence and with reservations, as it is doubtful whether the thyroid secretion should be regarded as a primary toxic influence directly causing the arthritis, or whether it may not be rather a secondary influence modifying a pre-existing joint infection. That it is the latter in some instances we have abundant evidence, but from time to time one meets cases which seem to suggest the possibility of the former theory. In the vast majority of recorded cases hyperthyroidism has been associated with the arthritis; in a very few cases only, hypothyroidism. Some connexion between thyroid activity and rheumatism has long been noted,[8] while Spender, I believe, first drew attention to an affinity between Graves's disease and rheumatoid arthritis.[9] Recently I have seen, and described elsewhere,[10] two cases exhibiting the jaw-neck syndrome, and clinically resembling ordinary toxic arthritis, which appeared to be caused by, or at any rate to be modified by, hyperthyroidism, and which cleared up under treatment direct to the thyroid. That they should resemble the toxic cases in exhibiting the syndrome is especially interesting in view of the possible toxic origin in Graves's disease of the thyroid condition itself. One extremely serious case in a middle-aged woman with " goitre and nerves," marked tachycardia but no exophthalmos, was treated by baths and medicines for three years with but slight benefit. The severe multiple arthritis cleared up rapidly with the application of oleate of iodine to the joints and ice poultices to the thyroid. The other case was that of a young girl of 18 with tachycardia and a slight soft goitre, and a condition of joints suggesting mild rheumatoid arthritis. Every conceivable treatment was tried without avail, until, on consideration of the occasional beneficial effect of suprarenal extract in exophthalmic goitre, despite the usually accepted view of the action of the adrenal secretion on the thyroid, she was finally given adrenalin by the mucous membrane of the lip, when the joints began immediately to improve, and the pulse-rate fell to normal.

Group C.

9. *Traumatic Arthritis.*—In the acute stage this is, of course, a surgical condition; in its final stage, unless complete recovery takes place, it is generally an osteo-arthritis. One variety of traumatic arthritis is occupational arthritis —in other words, arthritis due to repeated small injuries in one habitual direction, and is apt to be labelled chronic rheumatism. Closely allied is the secondary arthritis consequent on the abnormal stress of a distant deformity—e.g., the arthritis of a knee due to a flat-foot. It would seem rather absurd to call such cases rheumatic, and indeed they shade off inevitably and imperceptibly into Group D.

Group D.

10. *Osteo-arthritis.*—A condition wholly dissimilar from the rheumatoid arthritis defined in para. 6, and I would submit that in so far as the bony changes are concerned, it is not really a disease entity at all, but rather an end-process and final stage of many diseases, an effort of the system (not always too successful an effort) to limit and repair the ravages of disease or injury. It is characterised by osteophytic out-growth and by deposit of compact bony tissue, and would seem in some respects to afford a somewhat close analogy of function to callus. Just as callus acts as a splint to bone, so we may conceive osteophytic outgrowth as tending to limit the movement of damaged joints, thereby saving wear and tear of enfeebled tissues and giving essential rest in inflammation. Again, the deposit of compact resistant bony tissue would tend to limit the spread of infection. It occurs only in connexion with injured tissues[11] and under no circumstances will you find it arising *de novo* on an unimpaired surface. The face of the bone, or the articular cartilage covering it, may have been injured by any of the above forms of arthritis, or it may have suffered such gross injury as a fracture. In occupational arthritis the location and form of the resultant osteo-arthritis may at times be foretold with great accuracy by considering the nature of a man's employment; and conversely, the nature of a man's employment can sometimes readily be determined by the examination of the osteo-arthritic scars on his skeleton.[12]

Whether osteo-arthritis be monarticular or multiple, and whether the jaw-neck syndrome be exhibited, will depend on the number and nature of the antecedent lesions. Thus, in traumatic and occupational arthritis one joint, or a limited and definite group of joints, will be affected, while in osteo-arthritis secondary to gout or rheumatism, the lesions are likely to be multiple and the resultant osteo-arthritic deformity will be moulded by the antecedent disease. It was pointed out by Lane[13] that the amount of bone formation, represented by eburnation and bossing, bears a direct relation to the vitality of the osseous system. Thus in mollities ossium and Charcot's disease the arthritis is accompanied by little or no reparative changes. Hence, it may be remarked that, whereas in old gouty joints there is abundant bossing, in rheumatoid joints it is almost absent. It will be noted, too, that osteo-arthritis of the hip-joint is an exceedingly common result of the frequent small bruisings of the joint by the wear and tear of life, while rheumatoid arthritis of this joint is so rare that many observers have never seen a case.

Bearing of the Syndrome on Treatment.

I feel that some apology is due for the fact that the question of therapeutics has been kept somewhat in the background. In extenuation I would advance that, accurate diagnosis being a necessary preliminary to treatment, I have endeavoured, by suggesting a classification, at any rate to clear the ground for subsequent therapeutic measures. This provisional classification—and in the present state of our knowledge all classification must be provisional—is suggested, not for the sake of an appearance of logical completeness, nor from an academic splitting of hairs, but with a view to its practical utility in treatment.

The essence of treatment is first, if possible, to remove the cause, and then, if necessary, to mitigate its effects, to relieve the symptoms. By applying common habit of some of these animals to occupy the burrows of animals of different species and it was no uncommon matter to find the carnivorous mongoose and some of the smaller non-carnivorous rodents inhabiting the same series of burrows without detriment to the latter; it should be remarked, however, that in such instances the carnivore would be a day feeder while the non-carnivores would be night feeders.

The procedure devised in attempting to discover the presence or absence of sickness or mortality due to plague infection was to commence tracking and digging out operations close to the localities where human plague cases had resided or (what was subsequently found to be equally important) in the immediate vicinity of where the human cases had been engaged in agricultural occupations, such as ploughing, herding sheep, or camping for meal times. It was found important also to rapidly and widely extend the area of operations, because in the early investigations the burrows in the immediate vicinity of the residence or work place of the human cases had been found to be deserted by animals and fleas, or at most to contain only a few shrivelled remains of their former occupants from which it was impossible to determine the presence or absence of plague infection. As a result of very zealous and painstaking work, conducted on these lines, extensive sickness and mortality due to plague among some of the smaller species of rodents were at last discovered.

The procedure for verifying the nature of the infection and the safeguarding of the experts and their native labourers from the danger of flea-carried infection while engaged in laboriously exploring the ramifying burrows and the rodents' nests, presented some initial difficulties. Owing to transport difficulties it was considered impracticable to make use of a field laboratory. Arrangements were eventually made whereby a supply of ice and containers was kept constantly at hand for the transport without putrefaction of animals recently dead to a central laboratory for diagnosis, and as regards the danger from fleas, which were found in abundance, the use of insecticides, both personally and otherwise, was practised before the bodies or nests of rodents were handled.

The animals so far proved to be plague infected and to show a very heavy mortality over a wide area are, (*a*) Gerbille or *Tatera lobengulæ*, a rodent slightly larger and somewhat similar to the domestic brown rat. (*b*) Multimammate mouse or *Rattus coucha*, a rodent somewhat similar in size and appearance to one of the ordinary domestic mice. These two are thought to be perhaps the commonest of the animals contained in the above list, in the area of country under consideration, and they undoubtedly exist there in very large numbers. Burrows containing one or the other, and more often both species, extending in what may roughly be described as chain formation with occasional gaps, have been traced almost throughout the whole area. Both are animals which only venture out at night, and this fact and their habit of closing up the entrance passages of their burrows, may account for the failure of the earlier investigations and inquiries as to the presence of rodents in or near residences affected by plague. Both feed commonly on the young roots of vegetation, wild melons and the like, and both occasionally, and when pressed for food, eat grain. Neither lives in farm-houses or natives' huts, but the multimammate mouse is inclined to live in closer proximity to human habitations than the gerbille, and its burrows have occasionally been located by an expert in the backyards of farm-houses and close to the walls of native huts. Provisionally, then, this species may be accepted as being the common conveyer of infection to man in the area in question, but an instance has occurred where the evidence definitely points to human infection acquired from a gerbille burrow remote from human habitation. The person infected had been accustomed to sit daily for his midday meal on a spot honeycombed with gerbille burrows—from which subsequently definite evidence of gerbille infection was obtained. None of the other animals mentioned in the above list have been found so far to be plague infected, but the numbers of these captured and examined have been small and no experiments have been so far made to ascertain their susceptibility to plague.

Several means have been attempted to destroy these rodents, but the methods ordinarily applicable to "domestic" rodents are not generally practicable, owing to the vast areas involved, and to their habits of feeding and burrowing. Poisoning on a large scale appears to be inapplicable, having in view the nature and easy accessibility of their principal food. The use of sulphurous and arsenical vapours, either with or without special apparatus, met with scant success owing to the closing of burrow passages and the branching of the burrows. Where the entrances of burrows have been discovered and cleared some success was obtained by the use of carbon bisulphide in each opening, and the subsequent closing by turf. On subsequent excavation all occupants have been found dead, and the fleas, both on the rodents and in their nests, have been found in a more or less inactive state. The fatality to fleas is not so marked as the fatality to their hosts, and a dose of the vapour which destroys all rodents leaves a fair proportion of their fleas in a condition from which they recover. Trapping or systematic digging out in such an area is too vast a work to be seriously considered.

There remains for consideration the possibility of providing or increasing their natural enemies, or of discovering and spreading a disease among them which is not fatal to human beings. A careful collection of fleas and other ectoparasites found on each animal captured or found dead and in the underground nests was made. The results of their classification will be declared in due course. No experiments have hitherto been made to discover which of the varieties found are capable of transmitting the bacillus, but it may provisionally be assumed that the carriage of infection from rodent to rodent and from rodent to man has been effected in this area by one or other of the varieties found.

From the circumstances here described, and from the observations of experts on the spot, more especially from the discovery of large areas of rodent burrows entirely depopulated and containing only a few shrivelled remains, it appears probable that plague infection almost annihilates gerbilles and multimammate mice in any particular series of burrows infected, and that the epizoötic extends slowly across country in an irregular manner through chance visits of animals to burrows in the vicinity of their own dwellings, while a sufficient number may escape death to bring about a repopulation when the period necessary for the death of the ectoparasites in infected burrows has elapsed. Human infection from fleas which have deserted the dead rodents and their nests has been only an occasional occurrence, and has been commonest in those engaged in outdoor pursuits. As the area involved produces cereal foodstuffs and forage, which are sent in to the towns, and as long as wild rodent infection there exists, there must be faced the problems of preventing the transference of infected fleas or rodent remains from the collecting centres and railheads, the preventing of the extension of the town or domestic rat population to the area in question, as well as the general curtailment of the domestic rodent in the towns and ports.

The information obtained in these investigations appears to tally in some respects with the reports of infection of wild rodents by observers in other countries so well collected and set forth in Dr. Bruce Low's last report on the progress and diffusion of this and other diseases throughout the world 1914–17, and may further help to elucidate certain problems as to the existence of latent foci of infection, remaining perhaps almost unnoticed in remote rural areas, from which at intervals, and dependent on the extent and vulnerability of the domestic rat population, a serious epidemic affecting human life and trade may arise, traversing the routes of the transit of grain and other foodstuffs.

attack upon it, for infants of 6, 7, 8, 10, and 11 months have recovered under such treatment, and many children owe their lives to its careful use.

Resection of ribs is intimately bound up with the use of drainage-tubes, for it is well known that unless resection is done in the young the ribs will pinch the tube and bring about a condition analogous to premature removal of one tube, or too early closure of the wound.

It is clear from our analysis that, with all its disadvantages, resection and drainage is a valuable operation, and that any method chosen will, in some cases, meet with considerable and possibly unexpected *difficulties. It is also apparent that a method which* will diminish shock and suffering, and yet be effectual, will be a means of saving life.

Analysis of 71 Cases of Empyema in Infancy.

1. *Age and sex.*—Twenty-one cases were of 1 year and under, the youngest being 4 months of age, and 50 were between 1 *and 2 years. Forty-five were males and 26* females.

2. *Mortality.*—The death-rate in the first 12 months *was very high. Sixteen of the 21 succumbed, and of the* 50 over a year old 23 died. In percentages the death-rate in the first 12 months was 76, and between the first and second years, 46. The total number of deaths was 39, or 55 per cent. These figures closely approximate those given by Spence.[1]

3. *Clinical histories.*—It is remarkable, when the histories of these cases are examined, how long a time may elapse between the first signs of definite illness and the discovery of pus in the chest, and how frequently this happens. Allowing for errors and oversights, in many cases the early symptoms *are very indefinite, and we are left in doubt* as to when the actual development of the empyema occurred. For this reason we have empirically classified these cases into three groups: (1) Acute, with symptoms of under a week's duration, (2) Subacute, with a history of from one to three weeks' duration, (3) chronic, with a history of from three weeks' to eight months' duration. There were 13 acute cases (10 deaths); 13 subacute cases (7 deaths); and 45 chronic cases (22 deaths). From this analysis the importance of the virulence of the infection is apparent.

4. *Nature of infection.*—In 31 *of the 39 fatal cases* the *nature of infection was as follows:* 21 *pneumococcal*, 4 staphylococcal, 3 streptococcal, 3 tuberculous. In the remainder the causal agent was not stated. Taking all the cases: 43 were pneumococcal (21 deaths), 7 staphylococcal (4 deaths), 3 streptococcal (3 deaths), 3 tuberculous (3 deaths), and 1 sterile (recovery). In 14 cases the cause was not stated. From these figures it is apparent that the pneumococcal infection easily preponderates in the empyemata of infancy, and that the death-rate from this cause is close upon 50 per cent. In spite of this fact we would here repeat that the histories of many of these cases *as gathered from the case-books, often gave indeterminate* symptoms. The figures in which we have tried to express this point must not, however, be looked upon as of more than relative value. In 26 cases there was a clear history of pneumonia, in 7 of bronchopneumonia, in 7 of bronchitis; 6 were associated with measles and bronchitis; 1 with chicken-pox, and 3 with whooping-cough. In 20 cases, although respiratory symptoms and signs appeared, no *definite name had been given to the illnesses before admission.*

5. *Prominent symptoms in the histories.*—The prominent symptoms recorded in the pre-hospital histories were as *follows:* Cough in 38 cases, *vomiting in 24, dyspnœa in 23,* wasting in 23, pain in 8, cyanosis in 7, "fits" in 4. Of these the reiteration of vomiting, breathing trouble, and wasting, when coupled with cough, stands out as an indication in infancy for careful consideration of the possibility of the presence of an empyema. We believe that any group of symptoms in these difficult cases, which would help to remind us of empyema, would be of assistance, and we are led to this belief *from the record of the prominent signs* which were found in this series on admission to hospital.

6. *Signs on admission to hospital.*—In no less than 66 cases definite impairment or complete dullness was *discovered in* some part of the chest, and almost invariably at one or both bases. In 40 the breath sounds over these regions were absent or diminished. In 18 there was tubular breathing, and in 23 the heart was displaced. Crepitations were noted *in a few cases.* The well-known *fact may here be emphasised* that in infancy and childhood tubular breathing is frequently found over the site of an empyema—a fact apt to mislead those unacquainted with the occurrence. It is worthy of note that displacement of the heart is only recorded in 23 of the 71 cases, although it must be allowed that slight displacements in infancy are by no means easy to recognise decisively.

7. *Causes of death.*—The causative factors of death in the 39 fatal cases of our series constitute a question of great importance for prognosis and treatment. In 8 cases there was no post-mortem examination, and these must be *set aside, leaving 31, which we divide into three groups.*

Group 1.—Twelve cases, in which the empyema was either not detected, or, if it was detected, the child was moribund on admission. In 2 of these cases tuberculous meningitis was found, and in 3 suppurative pericarditis.

Group 2.—Eight cases, all of which were operated upon with resection of a piece of rib, but the necropsies showed the following complications: In 3 cases suppurative meningitis, in 3 suppurative pericarditis, in 1 lateral sinus thrombosis, and in 1 gangrene of the lung. In all these cases the lungs themselves contained either areas of pneumonic consolidation or some collapse. Both suppurative meningitis *and pericarditis occurred not only in cases with long histories,* but also in acute cases.

Group 3.—Eleven cases in children who either died rapidly from shock and collapse, or rallied for a day or two, and then—the wounds having become unhealthy and the temperature having again risen and persisted—they sank gradually, apparently from a lack of vital power to resist the infectious process. In this group we hoped to gain some success by the method described below, which minimises *shock and eliminates the open wound.*

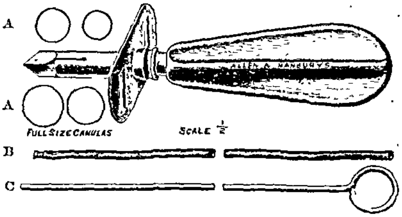
In a brief review of this analysis it becomes apparent that failure to detect an empyema is a factor in an adverse prognosis, but we do not presume to criticise this failure, realising well enough how deceptive the *symptoms may be and how difficult also the physical* signs. We would dwell upon cough, dyspnœa, vomiting and wasting as a combination of symptoms suggestive of an empyema. A certain proportion of *these cases demonstrate that a small empyema is only* one incident in a profound toxæmia, and is of no practical importance in the face of a virulent infection, damaging not only the lungs and pleuræ, but also the pericardium and meninges. It is, however, the cases that sink and die after operation that require special consideration, and have suggested the need of some method of treatment other than resection and drainage.

The Method of Continued Aspiration.

(A) *Apparatus.*—The apparatus and technique used by us have been devised with the special object of completely emptying the pleural cavity, and maintaining continuous drainage by aspiration without at any time exposing the cavity to the outside air and secondary infection. The apparatus consists of:—

(1) A straight round silver cannula, $\frac{5}{8}$ inch in length, provided with a shield through which tapes are threaded whereby it is kept *in position on the chest wall.* (Fig. 1A.)

FIG. 1.



Cannula and trocar. A A = Actual sizes of lumen of cannulas. B = Rubber tube. C = Introducer. *The trocar and cannulas* are made in four sizes by Messrs. Allen and Hanburys, Ltd.

(2) A trocar, with a short point, used for insertion of the cannula.

(3) A rubber tube (B) 10 inches long, having a slightly larger lumen than the cannula; one end of the tube is completely closed by tying it firmly with a silk ligature, and *immediately below this a hole* is cut in the tube, $\frac{1}{2}$ inch long, and involving half the diameter.

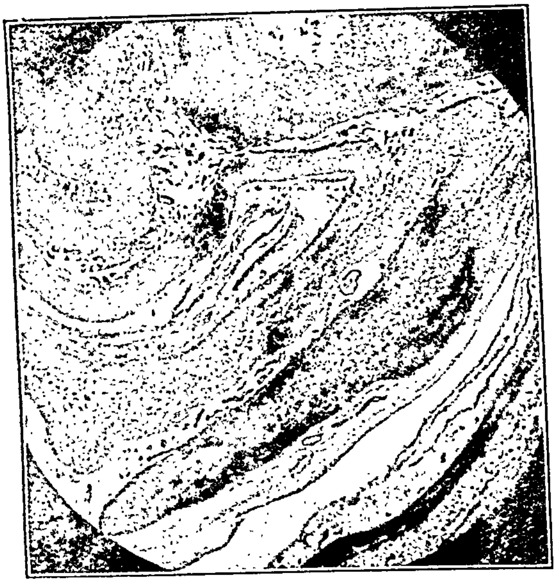
(4) An introducer (C) for the rubber tube, which consists of a metal rod that will easily pass into its lumen.

(5) A White's suction-pump, as used for suprapubic drainage.

the case of lesions in the mesencephalon, the respiratory irregularity is due to involvement of the mesencephalic respiratory tract described by Graham Brown. The purely cortical localisation of the lesions in the present case would explain the absence of this feature. There is no note of glycosuria occurring during the course of the illness, which is surprising in view of the statement that there is continued glycosuria in decerebrate animals (Mellanby[2]).

There is nothing to lead one to believe that the child suffered from any brain disease at birth or, in fact, before the onset of this fatal illness, and it would appear that the anatomical changes represent the effect of an inflammatory lesion of about two months' standing, the gross softening being due to occlusion of vessels. The peculiar distribution of the softening in the deeper layers of the cortex and adjacent white matter may possibly be explained by the arrangement of the cortical vessels, as described by Bignami and Nazari.[3] These authors state that the pia supplies two types of vessels, one short and one long, both of which penetrate the grey matter. The short vessels are purely cortical, whereas the long ones supply a narrow territory in the centrum ovale: anastomoses between these two types of vessels occur in the deeper laminæ of the cortex, and the richest capillary network is in the infra-granular layers. No spirochætes could be found in sections stained by Levaditi's method, and there was no real evidence of syphilis.

FIG. 2.



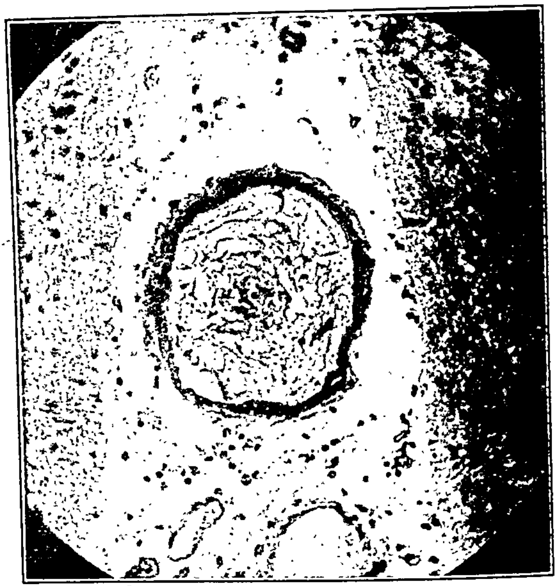
Showing the softening and absorption of the deeper layers of the cortex and adjacent white matter, and also the appearance of increased vascularisation. The swelling of the meninges is well seen. (× 10.)

We have been unable to discover any identical case in the literature of the last 20 years, and cases with even a slight similarity are rare. Sutherland and Paterson[7] have described two cases of "forebrain aplasia," in which the clinical picture appears to have been that of incomplete decerebrate rigidity. The macroscopic morbid anatomy appears to have been very like that of the present case, but the histological details are very meagre; it is stated that the vessels were "too numerous and too thick as regards their walls," but one cannot be sure whether the authors wish to imply that there was a new formation of vessels or that there was simply closer approximation of the vessels due to collapse of softened areas. No cause is assigned to the undue thickness of the vessel walls.

At the International Pathological Congress in 1911 Dürck[4] showed a case of almost complete calcification of the cerebral hemisphere and states that some of the vessels in the neighbourhood showed calcification of their walls. His case was that of an adult male idiot, and, as far as one can discover from his clinical description, there was no very definite rigidity throughout the course of the patient's life. Marchand,[5] in the discussion which followed the above-mentioned paper, brought forward a case of cerebral calcification associated with the presence of a racemose angioma, and emphasised the fact that calcification of the cerebral vessels is not uncommon in the neighbourhood of a chronic inflammatory focus.

Meier[6] reports a case of total softening of both cerebral hemispheres in an infant, aged 5 months. The clinical account is not complete, but he definitely states that there was opisthotonos and extension of the arms with flexion of all the joints of the hands; the legs were extended and the toes pointed downwards. The macroscopic findings at autopsy were very similar to those detailed above. Histologically there appears to have been separation of the cortex from the subcortical tissues by extensive softening. Apart from mention of excessive number, there is no note of the condition of the vessels. Here, apparently, was a case of the same type as that described in the present communication; the child was of approximately the same age, the illness commenced with vomiting and convulsions, and the duration was about two months. Whether the conditions seen in our case can be regarded as an early stage of the condition described by Dürck appears doubtful, but there seems no reason to doubt that had the patient survived, idiocy would have been the effect of lesions so extensive as those described above.

FIG. 3.



Showing the changes in a meningeal vessel. The lumen is almost occluded. The dark line internal to the adventitia corresponds to total calcification of the media. The somewhat excessive cellularity of the meninges can be well seen. (× 100.)

Throughout the examination we have been greatly indebted to Prof. Shaw Dunn for advice on details of histological and photo-micrographical technique, as well as for permission to make use of his notes of the condition found at necropsy. Our thanks are also due to Dr. Wynn for permission to make use of this case.

(*Continued at foot of next page.*)

This last case illustrates a difficulty which may arise from not fixing the cannula securely; with increasing experience this has not occurred in any other case of our series. In this connexion the nurses should be warned of the importance of seeing that the tube leading from the chest to the pump is quite free, so that, should the child turn over in bed, there will be no pull on the tube, which may dislodge the cannula.

(F) *Some previous investigations into treatment of empyema by aspiration.*—We repeat that the principle of this method is by no means new, for as long ago as 1873 Playfair advised aspiration, and his technique was used and described by Dieulafoy.[2] In 1891 Bulau[3] devised a form of syphonage through a small rubber catheter introduced by means of a trocar, and Perthes[4] used this method with the addition of a water pump to provide continuous suction. Many modifications have been devised,[5] some of which are simple and useful up to a point, others too complicated for general use. They all have the disadvantage that they do not prevent secondary infection of the pleural cavity, and this we know, as has been specially pointed out by Holt[6] in a series of 145 cases, is generally the cause of death by exhaustion from prolonged suppuration. When we consider the high mortality of empyemata in infancy and their frequency at all ages in childhood, we believe that the method of treatment described here will be a real assistance in diminishing the dangers.

SPORADIC OUTBREAKS OF PLAGUE IN THE UNION OF SOUTH AFRICA.[1]

BY L. G. HAYDON, D.S.O., M.B., C.M. ABERD., D.P.H.,

ASSISTANT HEALTH OFFICER, UNION OF SOUTH AFRICA.

SINCE January of 1916 occasional cases or small groups of cases of plague have been discovered at irregular intervals in the Orange Free State and neighbouring districts, occurring under circumstances which did not, until recently, disclose the method of the spread of infection. The number of cases and the circumstances under which the outbreaks occurred have from time to time been officially declared. In previous years well-defined epidemics of the disease had occurred at the ports and larger towns in connexion with well proved epizoötics in the "domestic" rat population, and following the courses of transit of grain and other foodstuffs in the usual way. These epidemics were satisfactorily dealt with by campaigns against the "domestic" rodents and the other usually effective methods.

The occurrences since 1916 have differed in character from these well-defined epidemics in the following particulars:—

(1) The outbreaks were confined to persons or small groups of persons living in rural areas less densely populated than the bulk of South Africa, and remote from larger towns and villages.

(2) Investigation and the closest inquiries failed to elicit the existence of "domestic" rodents at or anywhere near the scene of the outbreaks. The nature and structure of the farm-houses and native huts in which many of the cases lived was such as not to favour the existence of domestic rodents.

(3) The time intervals between adjacent groups of cases was irregular, being in some instances a few weeks, and in other instances as much as many months. The distances between the scene of such outbreaks as would at first sight appear to have a common source of infection were in some instances as great as 50 miles, the intervening population remaining unaffected and the closest investigation failing to elicit any connexion, personal or through verminous fomites, between the groups of cases. Many of the cases occurred in persons living on isolated farms of several thousand acres, and having limited intercourse with their neighbours.

The Central Health Department was faced with the problem of discovering either the source of infection common to these outbreaks, or the means of transference of infection from one case or group of cases to the next, over varying intervals of time and space in the unusual circumstances stated. The theory tentatively held, that latent infection could remain in ambulatory human cases to reappear and be passed on in virulent form after a considerable interval, had under the circumstances to be revised, and as the series of small detached outbreaks continued to occur up to 1921, Dr. Mitchell, the Secretary for Public Health, decided to have close investigation made into the species, habits, and morbidity (if any) of the wild rodents of the affected area, and for that purpose enlisted the aid of experts trained in the capture and classification of African wild animals. The following results were arrived at in the early months of 1921:—

The area of country involved with a radius of about 150 miles may be roughly described as flat or gently undulating plains intersected by watercourses which only contain flowing water for a few months of the year, but in the valleys of which occasional pools may remain longer. These valleys are fringed with low scrub and vegetation, varying from a few to several hundred yards in width. The soil generally is a light sandy loam. The indigenous vegetation is grass, patches of low scrub, wild melons and cucumbers and the like, which usually grow in such latitudes in plains with scanty rainfall. The area is divided into farms of from 1000 to 5000 acres, and is mostly concerned with the raising of sheep and the production of maize and other cereals. The human population, both white and native, is very sparse and widely separated. The conditions generally favour the existence of the smaller wild animals, especially rodents, which find harbourage by burrowing under the roots of grass and the low scrub.

The animals captured were as set out in the following list:—

Common name.	Name as determined by an official of the Transvaal Government Museum.
Gerbille or gerbil	*Tatera lobengulæ.*
Large-eared mouse	*Malacothrix typicus.*
Fat mouse	*Steatomys pentonyx.*
White-tailed mouse	*Mystromys albicaudatus.*
Tree mouse	*Dendromys melanotis.*
Dwarf mouse	*Leggada deserti.*
Striped field mouse	*Rhabdomys pumilio.*
Multimammate mouse	*Rattus coucha.*
Namaqua rat	*Rattus namaquensis.*
Golden rat	*Rattus chrysophilus.*
Ground squirrel or meer kat	*Geosciurus capensis.*
Spring hare	*Pedetes caffer.*
Yellow hare	*Lepus ochropus.*
Kolhaas	*Lepus zuluensis.*
Red hare	*Pronolagus.*
Suricate	*Suricatta.*
Stender mongoose	*Galerella caaui.*
Yellow mongoose	*Cynictis penicillata.*
Muishond	*Ictonyx striatus.*

Considerable difficulties were encountered in their capture and in the investigation of their habits, owing to the fact that many of them are strictly night animals and burrowers, necessitating the careful tracking of small spoor in the early mornings to and from water-holes and feeding-places. The burrows are often of considerable depth and extent, branching in several directions, while the ordinary heap of earth which one looks for as indicating a burrow inlet may be absent, the earth removed in burrowing being used to block up the passage behind the burrower. Entrances and outlets may be numerous and carefully concealed under overhanging bunches of grass or bush. It was, moreover, found to be a

[1] A paper presented at the Royal Society of Medicine, Section of Epidemiology and State Medicine, on Oct. 28th, 1921.

Formalin Results of Two Cases.

Specimen.	W.R.	Formalin.	Syphilitic history.	Clinical evidence of syphilis.
Case 3 ..	Negative.	Positive.	Admitted.	Suggestive.
Case 4 ..	+ + + +	Negative.*	Denied.	Very suggestive.

* Or ? very slightly positive.

In other words, it is highly probable that the formalin results of these two cases really agreed with the Wassermann test results, making the total agreements 10 out of 11, or over 90 per cent. Gaté and Pappacostas found 85 per cent. to agree, while Major J. Mackenzie[2] found 100 per cent. to agree in a series of 23 cases. On the other hand, A. Murray Stewart[3] in a series of 25 tests got 14 positive Wassermann reactions but no positive formalin reactions.

I am aware that a series of 11 cases is not of much value, and would have preferred to collect more. Unfortunately, I have not now the opportunity of continuing this research, so have decided to put together the little already done, especially in view of the fact that there is as yet little published evidence of the importance of this easily applicable test.

My thanks are due to Dr. D. Macmillan for coöperation in my tests.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OPHTHALMOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Nov. 11th, Sir WILLIAM LISTER occupying the chair.

Exhibition of Cases.

Mr. HUMPHREY NEAME showed a case of cyst of Krause's gland, and also a lad, aged 16, with papular formations in the lid. A third case was that of a boy with tuberculosis of the conjunctiva. He cycled from London to Southend for a holiday, arriving very exhausted. After his return to work, while stooping down, he felt something give way in his left eye, and since then he noted a progressive failure of sight in that eye, and in six weeks he could only perceive with it fingers held fairly close. In September last year there were swellings in the neck, and in March this year a cough started, with watering of the right (the sounder) eye. At a hospital his condition was diagnosed as Hodgkin's disease; no signs of tuberculosis were elicited in the chest, and the sputum showed no tubercle bacilli. During the past year he had lost a stone in weight, but during the last three months his weight had remained constant. Four months ago the left eye was removed for irido-cyclitis. The cornea was hazy, and the anterior chamber was filled with a whitish substance. Mr. Neame exhibited sections of this eye on the screen, showing cellular and fibrous material in the anterior chamber, and destruction of iris and ciliary body. A small portion of conjunctiva excised from the right eye a month ago showed fairly typical tubercle formation.

Mr. LINDSAY REA showed a patient on whom he had successfully performed a Poulard operation for ptosis. He also showed a case of angeioma of the retina.

Mr. P. G. DOYNE presented a patient with congenital malformation of the iris and anterior chamber. There was an absence of anterior layers of the iris in many places, and a hole in each eye through which the red reflex could be seen. The angle of the anterior chamber was malformed and seemed to be filled by a whitish substance, while strands could be seen running from the posterior surface of the sclero-corneal junction to the anterior surface of the iris.

Sir WILLIAM LISTER recalled a case of a man who had nine pupils, one fairly central, the remaining eight being ranged peripherally round it. Eventually the man developed glaucoma, probably due to a developmental defect at the angle of the anterior chamber.

Mr. M. S. MAYOU and Mr. TREACHER COLLINS discussed the probable causation of coloboma with a bridge.

Mr. C. F. HARFORD read a paper on

The New Psychology in Relation to Problems of Vision,

demonstrating a number of schematic diagrams. He said that the attention of the psychologist had hitherto been mainly directed to the anatomical and physiological aspects of the problems associated with vision. Parsons, in his "Diseases of the Eye," after tracing the processes of vision from the impressions derived from external objects to the cortex, had used these words: "Here the nervous impulse is transformed into a psychic impulse, which is not, and probably never can be, understood." Mr. Harford contended that psychology could render important help in supplementing physiology, and that psycho-analysis had thrown new light on human thought. The mechanism of what Mr. Harford termed "The Psyche" he subdivided into cognition, affection (the emotional result of cognition) leading to action. One diagram represented the "store-chambers of the Psyche," which Mr. Harford classified as results of careful observation, results of casual observation, amnesia of common life, pathological repressions, infantile impressions, and instinctive and hereditary factors. He laid particular stress on the emotional factor of the Psyche—i.e., the activator of each mental concept, which Bergson had named the "énergie spirituelle." Mr. Harford went on to discuss repression, association, dissociation, and apperception. The vision of the infant was only gradually evolved, not because of any organic defect in the structures concerned with vision, but because the awakening of the intelligence was a gradual process.

Thrombosis of Retinal Vein, with Hole and Star at the Macula.

Mr. ARNOLD WILLIAMSON read a paper on Two Cases of Thrombosis of a Retinal Vein, one showing a Hole, the other a Star at the Macula. He first referred to the careful paper on holes in the macula published by the late G. Coats, in which were summarised the various theories of causation. Monteith Ogilvie considered there were two factors concerned: the fact that the retina is thinnest at the fovea, and thicker around it than elsewhere, and the fact that waves of disturbance passing through the eye meet at the posterior pole and tear the fovea by "contre-coup." Fuchs attributed the appearance in traumatic cases to mild traumatic retinitis, the slight serous exudate rupturing the membrana limitans externa, and so causing the appearance of a macular hole. Coats believed œdema was the underlying cause, stating that a hole had never appeared less than 60 hours after the injury; also that opacity in the retina had been observed after injury in a case in which a hole subsequently developed. In 1908, however, Kipp and Alt had published, in the *American Journal of Ophthalmology*, a case in which a shot passed through the orbit, tearing the optic nerve and its sheath and entering the skull. On the following day the retina was whitish and vessels narrow, except for a vein passing from macula to disc. At the macula was a red deep round spot, one-third D; two days later the retina was more opaque. Four days later the eye was excised, and there was a large hole at the macula, surrounded by swollen retinal tissue. There was evidence of œdema everywhere. Kipp and Alt considered that the retina at the macula could be torn by contre-coup. Mr. Williamson showed slides of his own case because they made clear the dependence of the formation of a hole in the macula on the occurrence of sub-retinal œdema, associated with thrombosis of the central retinal vein.

A CASE OF DECEREBRATE RIGIDITY IN AN INFANT,

ASSOCIATED WITH DIFFUSE SOFTENING OF THE CEREBRAL CORTEX AND CALCIFICATION OF THE CEREBRAL VESSELS.

BY A. P. THOMSON, *M.C.*, M.B. BIRM., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN, GENERAL HOSPITAL, BIRMINGHAM; PHYSICIAN TO OUT-PATIENTS, CHILDREN'S HOSPITAL, BIRMINGHAM;

AND

A. PINEY, M.R.C.S., M.R.C.P. LOND.,
ASSISTANT PATHOLOGIST, GENERAL HOSPITAL, BIRMINGHAM;
DEMONSTRATOR IN PATHOLOGY, UNIVERSITY OF BIRMINGHAM.

FROM the clinical aspect this case appears to be one of complete decerebrate rigidity of the type to be expected after ablation of the cerebral cortex.

M. J. M., a girl aged 4 months, was admitted to hospital on Oct. 3rd, 1920, under Dr. W. H. Wynn, with a history of three days' illness, during which she had vomited all her food and had had twitching affecting the right side of her face and legs. She was an only child, and had been breast-fed and bottle-fed; as far as can be ascertained she was quite healthy until the onset of this illness. There was nothing to suggest syphilis.

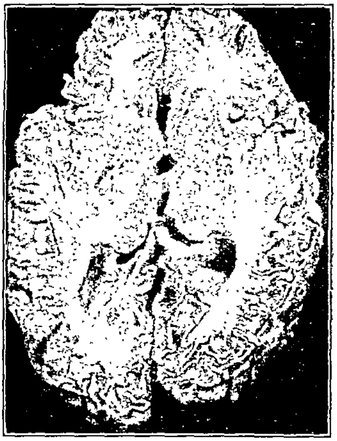
Condition on admission.—The infant was well developed and well nourished. She appeared unconscious, but occasionally rallied and seemed to take slight notice of her surroundings. The anterior fontanelle was distended, the conjunctival reflex was present, and the pupils reacted to light. The attitude of the child, when the bed-clothes were removed, was striking; she lay stretched out stiffly, with a slight degree of head retraction and opisthotonos. The arms were extended at the elbows, and held close to the sides, forearms pronated fully but not excessively, wrists strongly flexed, fingers strongly flexed at metacarpophalangeal joints, and interphalangeal joints extended. The knees were rigidly extended, thighs adducted, feet plantar-flexed, with the toes pointing downwards. The outstanding feature was the general rigidity, so marked that when the leg was raised in an endeavour to elicit Kernig's sign the whole body was raised, pivoting on the head on the pillow. The knee-jerks could not be elicited; the plantar responses were doubtfully extensor. Lumbar puncture was difficult to perform, as it was impossible to flex the spine. The child seemed entirely insensitive to the needle. The cerebro-spinal fluid was clear and under considerable pressure. Repeated examinations revealed no abnormality, with the exception of a doubtful increase of mononuclear cells. Cultures were uniformly sterile. The Wassermann reaction was not performed. Physical signs in the chest and abdomen were normal; the bowels were moved regularly.

Course of case.—The child's condition varied but little during the two remaining months of her life. She hardly ever appeared conscious and rarely cried; occasional twitching of the limbs was reported by the nurses, but it was always transient, and serious convulsions never occurred. The rigidity varied slightly; on some days the child would be slightly relaxed from the poker-like condition of admission, and she could then take feeds with difficulty. One remarkable change in the posture occurred about a week after admission: the feet, previously plantar-flexed, became dorsi-flexed, and at the same time the legs were rotated outwards, so that the feet came to lie heel to heel almost in a straight line across the body. After a few days the original position was resumed. The temperature was irregular; for no apparent reason it rose frequently to 101° or 102° F., and fell again within a few hours. There was no marked respiratory irregularity. The child died on Dec. 6th, 1920, after rather more than two months' illness.

The clinical features throughout the course of the illness appear to bear a close resemblance to the condition of decerebrate rigidity, as described by Kinnier Wilson, in man. The absence of gross respiratory irregularity in this case is explained by the peculiarity of the morbid anatomical findings described below.

Necropsy, performed on Dec. 8th by Prof. J. Shaw Dunn.—The body was that of an emaciated child; the calvarium was thinner than normal, and the medullary centres of the membrane bones of the skull were much congested. The dura mater was tense, and an excess of clear fluid escaped when it was opened. Inside the intact pia-arachnoid the brain presented a peculiar condition, in that large areas of the cerebral cortex had undergone an extreme degree of softening. A large area of this sort occupied the middle of the left temporo-sphenoidal lobe; similar but smaller areas were found in the other lobes of the cerebrum, no part of which presented normal appearances. On making a horizontal-transverse section of the cerebral hemispheres it was found that the softened areas contained much fluid, which ran out freely, so that the cerebral cortex with the pia-arachnoid collapsed, producing a shrivelled appearance of the surface of the cerebrum. This can be seen in Fig. 1, which is reproduced from a photograph of the preserved specimen. No lesions could be detected in the basal nuclei or in any other part of the brain, which had the ordinary appearances of infantile brain tissue. The right lung showed well-marked broncho-pneumonia in the posterior part of all three lobes. No evidence of tuberculosis could be found in the brain or in any other part of the body.

FIG. 1.



Cerebrum, showing the extensive softening of the deeper layers of the cortex and adjacent white matter. The most superficial part of the cortex is seen to be intact, and under this there is a continuous space; this can best be seen in the portion of the brain shown at the right-hand side of the figure. (Two-thirds natural size.)

Histological examination.—Examination of formalin-fixed material showed an almost complete destruction of the deeper layers of the cerebral cortex and adjacent white matter, the superficial cortex being thus severed from its connexions with the deeper parts of the brain. The softened areas had undergone almost complete absorption, and in the deeper part of the cortex and adjacent white matter there was only granular debris. This softening and subsequent absorption have brought the vessels into closer approximation, and so given rise to an appearance of excessive vascularisation. These appearances are well seen in Fig. 2. Many of the meningeal vessels lying in the sulci show a well-marked endarteritis obliterans which narrows, and in some cases obliterates, the lumina. The newly-formed tissue in the intima is loose and reticular in appearance, showing no formation of connective tissue of healthy type. Many of the vessels in which this type of endarteritis is present also show some degree of calcification in their walls; this process of calcification can also be seen in some of the vessels in which no endarteritis is present. In most of the affected vessels the calcification commences in the media, and in no case extends into the intimal thickening. The meninges in the sulci—and, to a less extent, over the gyri—show an ill-defined meningitis in that they exhibit newly-formed connective tissue and a small excess of mononuclear cells. These appearances are seen in Fig. 3. In the brain tissue there are a few foci of calcification which appear to bear no relation to the vessels.

Discussion.

There is one outstanding difference between the clinical picture of the case and the description given by Kinnier Wilson.[1] The present case showed no marked respiratory irregularity, which is described as part of the picture in cases due to transection of the mesencephalon. Kinnier Wilson suggests that, in campaign against them. Tuberculosis belonged to the latter group, and the recent campaign of notification and the dispensary and sanatorium had not yet had a fair opportunity of exhibiting its influence.

In considering the causes of the great reduction in tuberculosis, Prof. Collis remarked that the disease was a "*pestis pauperum*," being closely correlated with poverty. Underfeeding was probably the chief influence in this connexion, and this might be due to lack of vitamins as well as of calorific value in food. During the great war the lack of food and particularly of fat was accompanied by a marked rise in mortality from tuberculosis. In Prussia that mortality increased by 67 per cent. between 1913 and 1918, and rapidly fell later with the improvement in the food supply. It was found that in every country the disease rose amongst the civilian population with food stringency and fell when it ceased, while the armed forces, who were well fed, did not suffer in this way. Children of the breast-fed age also appeared to have escaped. The speaker then pointed out how the consumption per head of milk, butter, and sugar, but not of other foods, had risen in the past 50 years, while tuberculosis was declining. The increase in sugar was counterbalanced by the decrease in potatoes. This, and the figures for wheat, meat, bacon, and cheese, were against the idea that carbohydrate or protein foods were concerned, and pointed to the fat constituent of milk as being the important factor. The influence of milk had been explained (1) by the immunising effect of bovine tubercle bacilli, and (2) by its content of vitamins, particularly fat-soluble A. The latter appeared more probable. Prof. Collis then proceeded to discuss the opposite effects of increased infection and increased immunity due to infection, resulting from such conditions as the growth of population, its aggregation and industrialisation, and improved facilities for transport. He held that the greater resisting power of the white races as compared with the coloured did not show that white men had acquired a specific immunity. In conclusion, he referred to the inhalation of silica dust as presenting a case of definite sensitisation to tuberculosis, and gave an interesting summary of the case for regarding the presence of SiO_2 as a sine qua non in this connexion, the effect not being produced by silicates or by other forms of silicon nor by other kinds of dust.

Discussion.

Dr. F. E. Fremantle, M.P., remarked on the importance and difficulty of breadth of outlook, and said that it was unfortunate that historical studies usually did not go back more than 60 years. Undoubtedly tuberculosis was controlled by the question of wealth *versus* poverty, and vitamins might well be an important factor in this connexion. While vitamins were a subject of dispute amongst experts it was not advisable to make pronouncements to the general public. The forthcoming history of the war would deal with diet in relation to disease. He hoped that the society would soon form a Group for Industrial Diseases.

Prof. H. R. Kenwood (University of London) said that he considered that there was no evidence for Dr. J. Brownlee's view that the fall in tuberculosis was epidemiological and that a corresponding rise was to be anticipated in the future. No doubt tuberculosis was a deficiency disease, but he pointed out the difficulty of determining which particular factor included in the complex conditions of poverty was responsible for tuberculous mortality. In regard to food, deficiency of the food itself might be as important as that of its vitamin content.

Dr. R. J. Ewart (M.O.H., Barking) observed that the examination of recruits at Leeds had shown that at least 3 per cent. of the population had pulmonary tuberculosis without knowing it. He held that no system of examination of contacts would reach all these, and that complete segregation of cases was impracticable. He did not support Newsholme's view that the segregation of advanced cases in Poor-law institutions was an important cause of the decline of the disease. He agreed with Prof. Collis that food was a most important factor, but differed from other views he had put forward.

Dr. H. R. Wilson (T.O., Southwark) remarked that fatal cases were much more likely to produce secondary cases in the family than were mild cases. Mass infection was of great importance, and advanced cases ought to be segregated. If food was so important a factor the question arose whether good results might not be obtained by feeding up the patients at home instead of treating them in sanatoriums, which was so much more expensive.

Dr. F. G. Caley (T.O., Wandsworth) questioned whether good feeding was so efficacious from the point of view of cure as of prevention. He had been impressed by the number of people who were in the closest contact with infectious consumptives—e.g., bed-fellows—and yet did not contract the disease.

Dr. J. Sorley (T.O., Essex C.C.) said the more he knew of tuberculosis the less he understood it. No doubt the food question had considerable influence, but he doubted the conclusions drawn from the figures about food consumption put forward by Prof. Collis. A correlation ratio might be illustrative without being explanatory. He had seen many cases of tuberculosis in the affluent classes of society and they were often rapidly fatal.—Prof. Collis briefly replied.

MEDICAL WOMEN'S FEDERATION.

A meeting of the London Association of the Federation was held on Nov. 15th at the Elizabeth Garrett Anderson Hospital, the President of the London Association, Dr. Louisa Martindale, being in the chair. A discussion on

The Physician's Responsibility in respect of the Sex Life of the Patient

was opened by Dr. Constance Long and Dr. Sylvia Payne.

Dr. Long said that parents often brought children to the physician with complaints about masturbation or phases of lying or stealing or other marks of a neurotic disposition. These characteristics formed a well-known syndrome, originating in some psychic disturbance. In dealing with such a case she advocated that tactful inquiry should be made about the emotional atmosphere of the home. Investigation usually revealed some disharmony between the parents, and it was sometimes necessary to probe into the personal life of the forbears to obtain such an enlightened view as would secure an improved emotional environment for the child. She said that older children should never be allowed to share their parents' bedroom. Dr. Long dealt with the significance of masturbation in children. She defined masturbation as "self-generated eroticism" and said that it might arise from fantasy alone, without any friction, or from the contemplation of some representative object. The masturbation of puberty and adolescence was connected with tension both physical and psychical. At such a time, when the sex organs were developing fast, masturbation might be physiological and act as a safety-valve. Masturbation should not be punished; it would disappear with maturity, if the life led was normal. Dr. Long thought that medical students should have more definite teaching on the subject of sex relations before they encountered such problems in practice. Patients who asked advice on the subject of the frequency of coitus should be told that the mutual happiness and well-being of the two partners should be their guide.—Dr. Sylvia Payne said that the history of primitive races showed that the present-day attitude to sexual problems was largely the outcome of ancient taboos and customs. The advance in psycho-analytical investigation had shown us that the psychical side of sexuality was as important as the purely physical. Women in general practice were continually consulted by newly married women for dyspareunia. If no physical defect was found, the difficulty was usually due to ignorance or fear, and the treatment was psychical rather than gynæcological, combined with a few practical hints. Dr. Payne then dealt with the relation of self-control to repression, repression being primarily an unconscious process, while self-control was a conscious function associated with volition. In married life mutual understanding was the basis of self-control, and newly married people should be advised to discuss these matters freely together.

Dr. Mary Bell, Lady Barrett, Dr. Helen Boyle, Dr. Mary Gordon, and others also contributed to the debate.

NOTES ON THE FORMALIN BLOOD TEST FOR SYPHILIS.

BY C. SUFFERN, M.A. CAMB., M.R.C.S. ENG.,
A.M.O., NOTTINGHAM CITY ASYLUM; LATE H.P., DEVONSHIRE HOSPITAL, BUXTON.

THE value of this test lies in its simplicity. Blood is drawn in the usual manner as for a Wassermann test. In the following cases the blood was collected in a clean but not sterilised test-tube; the test-tube was stopped with cottonwool, and set in a rack for 24 hours at ordinary room temperature. The room used was not a heated laboratory, but either the consulting-room or the sitting-room. At the end of 24 hours the serum was decanted from the test-tube into another clean but not sterilised test-tube; a drop of ordinary commercial formalin was added, and the tube was plugged with cottonwool. (This, of course, could be done as soon as the serum had separated; 24 hours was merely a period dictated by convenience. Moreover, it is not absolutely necessary to decant the serum into another tube; the formalin can be added straight away to the supernatant serum.) The serum and formalin were then allowed to remain at ordinary room temperature as before for 24 hours, the period prescribed by Gaté and Pappacostas,[1] who discovered this method. At the end of this period observation was made as to the condition of the serum. Coagulated serum is a positive result; fluid serum is a negative result.

Part of the blood collected for the formalin test was received in a sterile test-tube and forwarded as a control to an independent well-recognised laboratory for the application of the Wassermann test. The following 11 cases were examined:—

CASE 1.—Female, aged about 30, of stunted growth, with no history of syphilis. X rays showed osteitis and periosteitis, and bowing of the tibiæ. Wassermann reaction (W.R.) negative. Formalin negative.

CASE 2.—Male, circ. 50, with no history of syphilis, but with symptoms suggestive of early G.P.I. and tabes. W.R. negative. Formalin negative.

CASE 3.—Male, 44, with a history of syphilis contracted 22 years ago. Was then treated for two months at St. Thomas's Hospital. Had now got rheumatoid arthritis, with two nodules (? gummata), one periosteal and one subcutaneous, on each elbow. Aching pains all over. Five depressed circular scars on glans penis. Tachycardia. Depression of bridge of nose, alleged to be due to trauma. Was put on pot. iod. gr. v. t.d.s., and five days later blood was collected. W.R. negative. Formalin positive. It is highly probable that a mistake was made with the formalin specimen by confusion of this with the following specimen collected at the same time.

CASE 4.—Male, 48, with unilateral pains in left arm and leg. History of "shell shock" three years ago, while patient was testing guns. There was an explosion and he was buried in a mound of ashes. At another time he was struck by the recoil and had the occipital part of his scalp cut open. Now he had a tumour (? osteophyte) on the right index. Frequent gastric crises in the last six months. No dyspepsia. Left spermatic cord thickened. Sleep bad, not due to pain. Ankle-jerks absent, plantar reflex flexor, knee-jerks and pupils normal. Alleged gradual failure of eyesight. Heart and lungs normal. Alleged dyspnœa on exertion. Patient very garrulous. Dental caries and gingivitis, buccal leukoplakia. No history of venereal disease. W.R. ++++. Formalin negative (or ? very slightly positive). See remarks under Case 3.

CASE 5.—Male, 57. No history of venereal disease. Two months' history of present complaint. "Influenza" at onset, followed by synovitis of both knees, feet painful and cold. In bed three weeks. Now both knees hot and swollen with synovitis, œdema of legs, nothing else objective in joints; sleep bad on account of pain; tachycardia, systolic murmur at apex not conducted to left, cardiac sounds blurred and weak. Teeth all recently extracted; appetite good, bowels normal. W.R. negative. Formalin negative.

CASE 6.—Female, 41, with no history of venereal disease (she was not asked). Two months' history of present complaint. Pain began in tibiæ, but now includes lumbar and right inguinal regions. Had "jumping pains" in legs for some weeks before pain in tibiæ. Pleurisy five years ago; looks ill and is dark below the eyes. Sclerotics bluish. General pigmentation. Chronic ulcer of scalp and cranium, alleged due to trauma. Pain and swelling in left sterno-clavicular joint. Liver reaches umbilicus; tympanites elsewhere. Appetite poor; losing weight; teeth bad. Had "floodings" in the last two months. Six children ("health good"). One miscarriage ten years ago. W.R. ++. Formalin positive.

CASE 7.—Female, 11. No history of venereal disease (not asked for directly). Eight months ago had sudden pain in hips, knees, and left elbow, which were red but not swollen. Was feverish four months; in bed six months. Now left hip shows dorsal dislocation; neck of left femur thickened, appreciable manually. Hard glands below left sterno-mastoid. No signs of congenital syphilis. X rays show periosteitis of left femur. W.R. negative. Formalin negative.

CASE 8.—Male, about 25. History of recent gonorrhœa. Now has a small papule (? gonorrhœal wart) on glans penis, thinks it may be syphilitic, and asks for a blood test. W.R. negative. Formalin negative.

CASE 9.—Male, 42. No history of venereal disease. Four or five years ago he had sudden pain in back, knees, and ankles, while doing army drill in England. In hospital six weeks, of which three were spent in bed; went back to full duty. Pains on and off ever since. Altogether nine months in hospital before being discharged from the army two years later, having much improved. Present attack began six months ago, and he has been in bed on and off, but not for more than five days at a time. Pain worst in shoulders and knees; has done no work (as clerk) for six months; has 30 per cent. pension. Nothing of importance elicited in past history and family history. Shoulders and right elbow crepitate; nothing else objective in joints; pain in neck, periosteal node on left tibial crest, left foot gives Babinski's reaction; right plantar reflex flexor. Knee-jerks very sluggish, ankle-jerks absent; Argyll Robertson pupils; no Rombergism. Sleep bad, but not on account of pain; teeth ground down, gums fair. Flatulent dyspepsia. Appetite poor, bowels normal, heart and lungs normal; no cough. W.R. ++++. Formalin negative.

CASE 10.—Male, 56. No history of venereal disease. Has had present complaint six years, much worse the last three years. "Shooting and stabbing" pains in both knees. Has not been confined to bed, and has not been off work; is now improving. Nothing of importance elicited in past history. Father had "chronic rheumatic gout." Nothing objective in joints. Sleeps badly on account of pain in knees. Knee-jerks and ankle-jerks absent; pupils inactive, right pupil "pin-point," left pupil larger; cardiac sounds impure, teeth poor; lingual leukoplakia. Appetite fair; dyspepsia and constipation; no cough. Pre-sternal seborrhœid rash. W.R. ++++. Formalin positive.

CASE 11.—Male, 47. History of venereal disease denied. Six months ago there was gradual onset of pain in knees, and from left knee to left hallux. In bed two weeks, off work 13 weeks, now improved. Had "influenza" more than once; last occasion was four years ago; nothing else in past history. Mother had sciatica and two sisters were phthisical. Patient's left knee now much limited in movement with chronic synovitis. Genua vara, and tibiæ curved outwards since the age of 16. Walks with a stick, sleeps badly on account of pain, which comes on just before midnight. Knee-jerks and pupils normal; cardiac sounds sharp; teeth foul; appetite very good and bowels regular; no cough, lungs normal. W.R. negative. Formalin negative.

Analysis of Results.

Out of 11 cases the blood tests agree in 8. Of the remaining 3 it is highly probable that two formalin tests were confused one with the other. These two gave results as shown in the following table.

Pathology of Fatal Cases.

Dr. J. W. McNee remarked on the unreliability of the statistics of fatality after arsenobenzol injection. Not all deaths from this cause were so reported. The vaso-motor effects were never fatal, so that little was known of their pathology. Dermatitis and encephalitis hæmorrhagica were due to the effects of the drug on the vascular endothelium. In fatal cases of exfoliative dermatitis hæmorrhages occurred in the lungs and these became infected by micro-organisms. Jaundice and acute yellow atrophy of the liver had recently been studied in Germany, and the view was held that the increased frequency of these complications in Germany since the war was due to the lowered standard of nutrition. Pathologically acute yellow atrophy appeared to be a toxic rather than infective condition.

Hepatic Efficiency Tests.

Dr. R. L. Mackenzie Wallis said that the observations on the toxicity of arsenobenzol compounds have been carried out with a view to determining, by means of certain functional tests of hepatic insufficiency, the effects of administration of these arsenical compounds. Where definite focal necrosis or acute yellow atrophy follows, the signs and symptoms are generally so obvious that confirmatory tests are seldom required. The aim has been to ascertain whether single or repeated doses of arsenobenzol derivatives can or do produce any changes in liver metabolism, and whether the effects are immediate or remote. For this purpose three tests have been applied—viz., the levulose tolerance test, already described, the lipase content of the serum, and the cholesterol content of the serum. Applying the levulose test to patients receiving treatment for syphilis it was found that one injection did not produce any rise of blood-sugar with one exception. The same result was obtained after six injections. When, however, the patients were tested 2–3 months after the last injection the levulose tolerance test showed a definite rise; further, the normal blood-sugar content was found to be raised, and in many cases accompanied by slight glycosuria. Six months after this disturbance of carbohydrate metabolism following arsenobenzol compounds, the liver appeared to have regained its normal function. The lipase content of the serum had proved a simple and reliable test for watching the effects of arsenobenzol compounds on the liver. There was a distinct and steady rise in the lipase content of the blood after six injections, and just as in the case of the levulose tolerance test, the maximum effect was observed three months afterwards. The test was applied to the serum obtained for the Wassermann reaction, and 2 to 4 c.cm. were required, the method used being that described by Whipple and others. The cholesterol content of the serum appeared to run in opposition to the lipase content, the amount decreasing with the corresponding increase in the lipolytic activity of the serum. This relationship between cholesterol and lipase was of particular interest and might provide a possible explanation of the changes in the Wassermann reaction following treatment. The results demonstrated the following points—viz., the toxic action of arsenobenzol compounds was exerted sometime after treatment was suspended, and it appeared inadvisable to recommend a second course of treatment within six months of the previous course. If such was necessary and unavoidable then these tests should be applied, and the nature and dosage of the drug regulated accordingly. Cases showing evidence of previous hepatic damage should also be treated along the same lines. Since arsenobenzol compounds produce changes in the liver with disturbance of carbohydrate metabolism, it is advisable to test the patients for glycosuria three months after the last injection. In order to avoid unfavourable results, it would appear advisable to regulate the diet so as to avoid any undue strain upon the liver, particularly towards the end of a course of treatment.

Scheme of Treatment.

Dr. H. MacCormac said that in treatment there were two points to be considered: (1) the patient, (2) the disease. It was not much advantage to the patient to be cured of the disease if he were severely poisoned by the treatment. Primary and secondary cases could be cured, but in tertiary and late cases he had yet to discover any form of treatment that would render the Wassermann reaction permanently negative. Salvarsan, he thought, merely reduced a raging fire of infection to a smoulder; he therefore relied on mercury to complete the cure. For early cases he pushed the treatment; for the first week he gave 0·6 g. of N.A.B. intravenously, combined with 1 gr. of mercury intramuscularly, and for each succeeding week up to ten weeks, 0·9 g. of N.A.B. with 1 gr. of mercury. This was followed by an intermittent course of mercury for two years. He maintained that mercury gave the only certainty of cure, and quoted cases treated in the early days of "606" by only two or three doses of "606" followed by two years of mercury treatment which still appeared cured. It was hardly probable that two or three doses of "606" had achieved this. For late cases he prescribed a short course, followed by occasional treatment as symptoms arose. He personally preferred the intravenous method of administration of arsenobenzol compound to the intramuscular.

Animal Experiments.

Dr. H. H. Dale did not agree with Colonel Harrison as to vaso-motor effects not occurring in animals. By animal experiments the vaso-motor effect of each batch of arsenobenzol could be accurately determined. Owing to toxic effects in animals manufacturers had, at one time, turned their attention to the reduction of toxicity, with the result that the therapeutic value of the drug was lowered. It was then established by further animal experiments that the vaso-motor effects and therapeutic value of any batch were parallel. Both effects were due, he thought, to the slow production of arsenious oxide in a colloidal state in the blood, and the vaso-motor effects were of an anaphylactoid nature. The toxic effect on the liver was due not to the arsenic, but to the organic portion of the arsenobenzol molecule; it very closely resembled that seen in tri-nitro-toluol poisoning. Animal experiments showed that silver salvarsan had the greatest therapeutic effect.

Arsenobenzol Poisoning.

Sir William Willcox had seen many fatal cases of arsenobenzol poisoning and agreed that cases were commoner than was supposed. The effects observed were very similar to those of tetrachlorethane, tri-nitro-toluol, and other organic poisons, and could therefore not be due to the arsenic portion of the molecule; indeed, inorganic arsenic in fatal doses had no effect on the liver. Death in toxic jaundice and acute yellow atrophy was due to auto-intoxication following liver insufficiency. When cases of acute yellow atrophy recovered, as a few had done, the enlargement of the liver gave place to a shrinkage, accompanied by ascites; this was due to replacement fibrosis of the degenerated area. In conclusion, he said he was staggered by the dosage of arsenobenzol recommended by one of the previous speakers.

Colonel Harrison, in reply, said he thought batches of arsenobenzol compounds which exhibited marked vaso-motor effects should be specially noted and given very dilute. As regards a scheme of treatment, he had found from experience that a rest for a week at the third and fifth weeks was advisable.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

A meeting of this Society was held on Nov. 9th, Mr. Cyril H. Walker, the President, being in the chair, when Dr. Cecil Clarke opened a discussion on

Renal Efficiency Tests.

His remarks were based on a series of 50 cases carefully investigated in association with Dr. J. O. Symes, at the

The first patient was a woman aged 62, whose sight began to fail 14 years ago. For two years, until excision of the eye in July last, she had continual pains in the head. The eye was excised because of absolute glaucoma. Thirty years ago she had a fall, blacking both eyes, but the sight was not impaired. The excised eye showed a corneal nebula, a cellular exudate adherent to the posterior surface of the cornea in places, hyaline exudate passing round the lens and causing some adhesion of the iris to it. There was no cupping of the disc. Sections were exhibited on the screen by means of the epidiascope, when there was an absence of the inner nuclear layer and inner reticular layer, and the retinal pigment layer was separated from the inner layer of the choroid. There was also some œdema in the outer molecular layer of the peri-macular region. The special point was that the cyst was formed not in the retina, but in the accumulation of œdematous material between the membrana limitans externa and the retinal pigment layer. In consequence of the presence of this cyst the outer layer of the retina appeared to undergo a degenerative process, so allowing of the formation of a hole.

Mr. Williamson also demonstrated a second case. In both cases there seemed to be a toxic influence, as shown by the irido-cyclitis, acting on the retinal veins and producing thrombosis, and acting on the delicate macular choroidal capillaries causing degeneration of their walls, increased permeability to fluid, and hence œdema. The fluid then osmosed through the potential space between the rods and cones and the pigment epithelium, preventing the access of nutrient materials from the choroido-capillaris, so that the superjacent retina degenerated and formed a hole.

Mr. **MAYOU** showed slides from a typical case of of albuminuric retinitis, showing exudation from two sites: inter-retinal and sub-retinal. The albuminous fluid in the layers of the retina was, he thought, derived from the retinal vessels, but the sub-retinal fluid from the choroidal vessels was of differing consistence, and responded differently to the stain.

SECTION OF PATHOLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Nov. 15th, Prof. **LAZARUS BARLOW**, the President, being in the chair.

Dr. W. E. **GYE** communicated the results of work undertaken by him in association with Dr. W. J. **PURDEY** on the Poisonous Properties of Colloidal Silica.

Mr. A. T. **GLENNY** read a paper by himself and Miss K. **ALLEN** on

A Guinea-pig Epizoötic Associated with Dietary "Deficiency."

Owing to a failure in supplies no green food was available and guinea-pigs for a period of six weeks had mangolds only in addition to the basal diet of bran, oats, and hay. Immediately after the commencement of this diet a slight increase in death-rate occurred. Two to four weeks later the death-rate increased rapidly reaching to between 15 to 20 per cent. per week. The first animals to be affected were pregnant does, experimental and small animals. During the first four weeks the post-mortem and bacteriological examinations showed typical Gaertner infection, with a few cases of pneumonia during the third and fourth week. During the fifth and sixth week 76 per cent. of the deaths were due to bronchial pneumonia caused by *Bacillus fæcalis alkaligenes*. After the introduction of green food fresh cases of infection did not occur, and the death-rate reached the normal level of under 1 per cent. per week within two weeks. A series of experiments were performed showing that swedes were of more feeding value than mangolds, and that the presence of an efficient diet such as green food would entirely control the epizoötic. During these experiments no attempt was made at isolation; the animals used were all fed, cleaned, and handled by the same assistant, and the presence of deaths in the "deficient" cages and the absence of deaths in the "full diet" cages were sufficient to show that isolation was of little importance in the prevention of spread of infection.

Prof. F. **HOBDAY** discussed the Pathology of Cleft Palate in Animals, showing specimens and illustrations.

Mr. J. B. **BUXTON** and Mr. **GLENNY** described

The Active Immunisation of Horses against Tetanus

by means of mixtures of toxin and antitoxin. Five hundred horses tested had no normal tetanus antitoxin. An injection of 10 c.cm. of toxin containing in all 20 "test doses" and definitely over-neutralised with antitoxin was given three times at intervals of three days. A month later an immunised horse would tolerate a dose of toxin upwards of 2000 guinea-pig lethal doses, which was probably equal to several hundred horse minimum lethal doses. This method proved of great use in the large scale production of anti-tetanic sera during the war. In order to demonstrate to the War Office that it was possible to immunise army horses against tetanus arising from wounds, four horses were immunised with two or three injections of the mixture; about two months later they tolerated, without any symptoms of tetanus, 2 c.cm. of actively growing culture of the laboratory routine toxin-producing strain of tetanus, together with a suspension of sterile garden soil. A dose of 0·02 c.cm. killed rabbits and guinea-pigs. Smaller doses were not tested, though the toxicity probably went very much lower.

Dr. H. J. **SUDMERSEN** read a paper by himself and Dr. A. J. **EAGLETON** on the

Standardisation of Anti-Dysentery Serum.

The method had been in use at the Wellcome Physiological Research Laboratories for some 10 years. 1·0 mg. of dried dysentery (Shiga) bacilli, which was equal to 10 intravenous lethal doses for an 1800 g. rabbit, was mixed with dilutions of the serum to be tested, and after half an hour was injected intravenously into a rabbit. The rabbits that failed to survive died with the well-known syndrome of ascending paralysis and diarrhœa. The amount of serum necessary to neutralise the test dose of toxin was called one unit. Sera of some 400 units had been produced. The agglutinative did not run parallel to the real protective antibodies; it was therefore fallacious to accept the agglutinin titre as an indication of the therapeutic value of a serum. Charts of various horses showed that sera might have an agglutination titre of 2–4000 while possessing no protective antibody.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AN ordinary meeting of this Society was held at 1, Upper Montague-street, W.C., on Nov. 18th, Dr. W. J. **HOWARTH**, the President, being in the chair. Thirty-two new members and four associates were elected.

Prof. E. L. **COLLIS** (Welsh National School of Medicine) delivered an address, as president of the Tuberculosis Group, on

Tuberculosis—Infection, Immunisation, Sensitisation,

in which he considered the causes which had brought about the great fall in tuberculosis that had occurred since the early part of last century. The disease was indefinite both in its clinical course and in its epidemiology; thus contrasting with such diseases as scarlet fever, mumps, and influenza, which had a definite incubation period, and ran a definite and short course clinically in the individual and epidemiologically in the community. Unlike these diseases, tuberculosis was "positively correlated" with the general death-rate. In this respect it resembled pneumonia. Clinical and epidemiological evidence suggested that in the case of tuberculosis, immunity, such as occurred with other infectious diseases, existed (it definitely did in the case of pneumonia), but was difficult to establish. The speaker rejected the theory that tuberculous invasion in the adult was to be ascribed to infection in early life. While certain diseases, like small-pox and leprosy, had been brought under control by specific measures (vaccination and isolation), others, like malaria and typhus, in this country had been reduced without any definite

Reviews and Notices of Books.

AN INTRODUCTION TO BIOPHYSICS.

By DAVID BURNS, M.A., D.Sc., Grieve Lecturer on Physiological Chemistry in the University of Glasgow. With a Foreword by D. NOEL PATON, M.D., LL.D., F.R.S. London: J. and A. Churchill. 1921. With 85 illustrations. Pp. 435. 21s.

Prof. Noel Paton in a foreword to this splendid book points out that as long ago as 1878 physiology was defined as the application of physics and chemistry to the study of the body in action. At that time the application was limited, because ionic dissociation was scarcely recognised. Graham's work on colloids not appreciated, and surface-tension phenomena not yet applied to molecular physics. Phenomena were recorded rather than explained—that is, "what happens" instead of "why it happens." The incorporation of physics and chemistry into physiology has led to its division into biophysics and biochemistry. Dr. Burns, who is now professor of physiology at the University of Durham, discusses only the physical aspect and explains, as far as is at present possible, the various life processes in terms of physical laws. He divides his subject-matter into five sections: (1) energetics, (2) cellular mechanics, (3) cell communities, (4) transport, (5) the animal as a whole; excellent illustrative experiments are given in the last part of the book.

Energy is the underlying cause of all changes in matter; no change occurs without free energy. The laws and kinds of energy are explained by Dr. Burns, and a useful scheme is drawn up to show that the total energy of the universe is partly free kinetic energy, available for work, and partly energy not directly available, of which some is lost as heat (entropy) and the remainder converted into free energy on being started by kinetic energy. The author shows that a continuous supply of energy is demanded for life processes, and that this is derived from the kinetic energy of the sunlight, which is converted into potential energy by the chlorophyll of the plant and forms our foodstuffs. Energy is measured in terms of heat; every foodstuff is ultimately changed into heat, undergoing various changes in the process. It is erroneous, according to Dr. Burns, to consider the animal as a heat engine which works between wide ranges of temperature to convert potential into kinetic energy; it is a much more complicated system, deriving its kinetic energy from the products of digestion by physico-chemical processes in solution. Substances in solution exert an osmotic pressure (kinetic energy) comparable to gas pressure, which is due to the bombardment of the molecules on the walls of the containing vessel, and at the same time alters the surface-tension of the liquid, at the surface of which, in contact with air or any other medium, there exist electrical charges.

Dr. Burns goes on to describe the three classes of substances which may be present in solution—non-electrolytes, electrolytes, and colloids. The dissociation of electrolytes, with slight changes in hydrogen-ion concentration, governs the osmotic pressure and produces changes in the surface-tension. Colloids with their large surface function act as a storage medium of potential energy: adsorbed salts are rendered osmotically inactive and by their property of imbibition they can act as reservoirs of hydraulic pressure. Enzymes, which are probably colloidal in their nature, produce alterations and can act as contact agents, ionic catalysts, or carriers. The cell membrane is affected by these changes either by a change in itself from within or by materials presented from without, and its permeability is so altered that material can pass in or out. Dr. Burns shows that while originally all these changes took place in a single evolution has elaborated special groups of cells ecific purposes. The muscle cells convert al energy into kinetic energy and heat in three Surface energy is the form of energy associated with muscular contraction. As the researches of A. V. Hill have shown, lactic acid is set free and produces alterations in hydrogen-ion concentration and surface-tension; oxygen is not required at this stage, but is utilised in the second stage of restitution in which carbon dioxide is evolved and lactic acid returns to the muscle substance.

Several physical processes are concerned in the numerous functions of the blood. Clotting seems to consist in the liberation from blood cells or tissues of kephalin, peculiar in its colloidal properties; it forms a surface upon which the thigmocytes in presence of calcium spread themselves and rupture, to set free thrombin and the consequent formation of fibrin gel from fibrinogen sol. The crystalloid concentration is maintained largely by the colloidal properties of the globulins; the chief salt of the blood, sodium bicarbonate, is concerned as a buffer from its power of neutralising acid. Association of oxygen with hæmoglobin is a function of partial pressure of gases; the dissociation being helped by temperature and especially by acid. The gaseous exchange in the lungs is by diffusion, though in special circumstances secretion may occur. Gas exchange at high altitudes and at high pressures (diving) is also considered.

These are only the briefest summaries of the wonderfully succinct account of the functions of all parts of the body from the physical aspect given by Dr. Burns. A final chapter is contributed by Prof. E. P. Cathcart on the efficiency of the animal. The physics and physical chemistry of osmotic pressure, ionisation, colloids, hydrogen-ion concentration, partial pressure of gases, and other phenomena are all separately and carefully explained, so that the reader can easily follow their application to physiology. The book cannot be too highly recommended, for it gives in a concise and interesting form a description of most of the modern problems in physiology.

THE HOT SPRINGS OF NEW ZEALAND.

By ARTHUR STANLEY HERBERT, O.B.E., M.D., B.S. Lond. London: H. K. Lewis and Co., Ltd. 1921. Pp. 284. 15s.

NEW ZEALAND abounds in natural springs, both hot and cold, of high remedial value, and Dr. Herbert, who writes of them, has had intimate experience of them for many years as Government balneologist at Rotorua, the principal health resort in the North Island. His book is conveniently divided into three parts: the first part descriptive and containing numerous excellent full-page photographs of the thermal regions with geysers in action, and chapters of Maori life; the second part giving the composition of the various waters and their effects; the third part setting out the author's deductions on general principles.

Rotorua as the leading spa of New Zealand receives most attention. Here the Government has effectually assisted the natural development by building a fine sanatorium with modern baths and appliances, in which the famous Rachel-spring water is applied. Various other spas, such as Helensville, Te Aroha in the North and Hanmer in the South Island, are touched upon more lightly, and mention is made of potential spas such as Kamo, Waiwera, and the high bracing resorts of Wairakei and Taupo. It is quite obvious that these resources have not been utilised as yet to anything approaching their real extent, and that New Zealand has a great asset in her climate and medicinal spas, which if developed in the future will place her in the front rank of the world's health resorts. At Ohaewai, for instance, the hot water and steam have decomposed the cinnabar ore, so that mercury has been deposited in visible metallic globules in the hot mud, a combination which, as the author remarks, would excite the envy of the authorities at Aachen. Taupo offers a combination of hot sulphur and chalybeate waters with alpine climate, for which the only parallel can be found in the Engadine.

An interesting chapter in the second part of the book deals with the classification of "rheumatic"

MEDICAL SOCIETY OF LONDON.

A MEETING of this society was held on Nov. 21st, Mr. JAMES BERRY, the President, in the chair.

Colonel L. W. HARRISON opened a discussion on the

ARSENOBENZOL TREATMENT OF SYPHILIS.

He said that he proposed to confine his remarks to (1) a comparison of the different arsenobenzol compounds and methods of administration; (2) the toxic effects following administration of arsenobenzol; and (3) the extent to which arsenobenzol should be employed in the treatment of syphilis. Comparing the different compounds, Colonel Harrison considered that the modern "606" is not nearly so effective therapeutically as the preparation first given out in 1910. The latter was certainly more toxic, but elimination of toxicity seemed to be accompanied by some loss of therapeutic efficacy. The modern "606" was superior in efficacy to "914," and sodium salvarsan seemed to be between the two. Silver salvarsan seemed so far to have borne out the claims made for it—that it is about twice as effective as "914" in similar doses. Colonel Harrison had been pleased with its effect on the cerebrospinal fluid in syphilis of the central nervous system, even in general paresis. The method of administration influenced the therapeutic efficacy. In the early days "606" was given subcutaneously. Much of the dose was buried in necrosed tissue and lost, yet the effect was at least equal to that of a dose of 0·6 g. given intravenously. Subsequently Wechselmann claimed that the subcutaneous injection of neosalvarsan produced better results than the intravenous injection. This was confirmed by Harrison, White, and Mills in 1917. The disadvantage of the pain was overcome by the use of sulfarsenol, a similar preparation to "914," which caused no more pain than did an intramuscular injection of mercury. Colonel Harrison did not recommend sulfarsenol for intravenous injection, but its use subcutaneously had given him excellent results, especially in old cases with a strongly positive W.R. It offered a hope of treating syphilis for long periods without fear of toxic effects, because it was possible that smaller total amounts might effect our purpose.

Toxic Effects.

The various toxic effects fell into different categories. Those due to damage of vascular endothelium included (*a*) the vaso-motor symptoms; (*b*) the so-called encephalitis, hæmorrhagic nephritis, and cases of purpura hæmorrhagica; (*c*) dermatitis; and (*d*) damage to parenchyma of liver. Vaso-motor symptoms followed intravenous injections and seemed to depend on the physical state of the solution when injected. "606" was more prone to cause vaso-motor symptoms than "914," and silver salvarsan almost always upset a patient unless fairly well diluted, say to 10 c.cm. for each decig., and given fairly slowly. Of the "914" class of preparations those which dissolved with difficulty were more liable to upset the patient when given concentrated than the less soluble. It did not follow that a preparation which caused vaso-motor symptoms was necessarily bad. Sometimes it was therapeutically better than the preparation which caused no upset. It was unfortunate that animals were so insusceptible to vaso-motor effects, because a preparation might be issued to the public with an excellent record as judged by toxicity and therapeutic tests on animals, and then might have to be rejected because it upset patients when given rapidly in a concentrated form. Such a preparation could usually be given safely if well diluted, say to 10 c.cm. for each decig. In regard to vaso-motor symptoms and to reactions, such as severe diarrhœa and vomiting, it was a sound plan to inquire carefully into the technique and the quality of the reagents. The contents of the bottle labelled "Sterile distilled water" were not always so fair as the label implied, and mixing vessels and syringes might bear on their walls that which might upset a solution very badly. Dermatitis had become extraordinarily infrequent since the war, and this was possibly because the average patient was now less exposed to climatic vicissitudes. Dermatitis was very rarely associated with polyneuritis. One or two cases of aplastic anæmia had been recorded in cases of dermatitis, and Moore and Keidel had recently drawn attention to the destruction of leucocytes originating in bone marrow. The only reliable method of avoiding dermatitis was by taking warning from small signs of intolerance. The man who injected a dose of arsenobenzol week after week according to a set programme and without a careful scrutiny of the patient before each dose was subjecting his patient to an unnecessary risk. Jaundice seemed to be in a different category to the other toxic effects. Its likeness in many features to the liver disturbances caused by T.N.T. made it possible that we should ascribe it to arsenobenzol rather than to arsenic alone. Many features of jaundice made it probable that there was an adjuvant factor in its causation. Thus fatal jaundice had occurred at a certain period in a very few military hospitals, and in one of these it had happened in only one section. This occurrence of fatal jaundice in little groups resembling small epidemics had been experienced in other countries. There was much obscurity about the whole subject, and it was to be hoped that the biochemists would evolve a practical test of liver intolerance or even a preventive treatment, so that we could give as much arsenobenzol as was necessary to cure syphilis without fear of the hidden danger of serious hepatic disturbance supervening at a later date.

Arsenobenzol Compounds and Mercury.

With regard to the extent to which arsenobenzol should be used in the treatment of a case of syphilis, Colonel Harrison considered that the reliance now being placed in this country on mercury for continued treatment of syphilis after the W.R. had become negative was not justified by the past record of mercury. In 1913 he had shown in the case of over 400 soldiers that two years' treatment by mercury only left over 40 per cent. positive to the original, and over 70 per cent. positive to Stern's test. If mercury were our only remedy to-day we should be treating cases not for two years but for four or five. Nobody knew how much activity was hidden behind the veil of a negative W.R., but it might be considerable; we were not justified in thinking that, when the W.R. had been rendered negative, mercury would complete the cure. Colonel Harrison held that we should treat syphilis by the chronic intermittent method for many months after the W.R. had been rendered negative, and that arsenobenzol should be used in the continuation treatment as in the early stages. Otherwise we should require a longer period for the cure of syphilis than the patient was likely to allow us.

DISCUSSION.

Prof. H. MACLEAN said that a number of experiments had been performed with reference to the rôle of the liver in toxic jaundice due to arsenobenzol. It was found that after the ingestion of most sugars the blood-sugar rose rapidly from the normal figure of 0·10 per cent. to 0·17 per cent. in about an hour, but after this a rapid fall occurred below normal owing to the action of the liver in storing carbohydrate. When levulose was given, however, the blood-sugar remained remarkably constant at about the normal 0·10 per cent., unless the liver were inefficient when it rose to 0·15 or even 0·18 per cent. Such a rise was found to occur in arsenobenzol jaundice. Even a small dose of arsenobenzol was found to affect the blood-sugar curve. He thought this levulose test might be useful in prognosis, and in one case had given a truthful prophecy of a good result from treatment when the clinical outlook had been grave. The liver was less likely to be affected by arsenobenzol when it was in a healthy condition and carried its normal glycogen content; some of the disasters that had followed the use of arsenobenzol were due to its being given to ill-nourished and even starving patients. To such patients he advised giving 50 g. of glucose about an hour before the injection.

bag is surprising. In view of the uniformly good results given by the use of bougies, especially when several are introduced and care is taken to separate the membranes round the internal os, there would seem no advantage in the unnecessary repeated interference which manual dilatation entails. Some of the other articles would have been improved by being brought more fully up to date, for instance that on Cæsarean section, but the originals were so good that we can understand a disinclination for change. The article on the resection of the sacral promontory, an operation which we thought had long ago been entirely abandoned, might well have been omitted.

In spite of these criticisms the whole may be regarded as an excellent guide to a practical knowledge of the subject with which it deals.

JOURNALS.

BIOCHEMICAL JOURNAL. Vol. XV., No. 4. 1921.—Some Observations on the Hæmolytic Action of Certain Quinine Salts on the Erythrocytes of Different Individuals and on the Resistance of Newly-formed Red Corpuscles to Hæmolysis under the Influence of Distilled Water, by U. N. Brahmachari and P. Sen. (1) Quinine salts are less powerfully hæmolytic than equimolecular solutions of the acids they contain: glucose seems to inhibit the hæmolysis produced by quinine. (2) The resistance of the fowl's corpuscles to water hæmolysis is increased after repeated bleeding.—A Method of Estimating Phenylhydrazine Volumetrically and its Application to the Estimation of Pentosans and Pentoses, by A. R. Ling and D. R. Nanji.—On Carrageen (*Chondrus crispus*). II. On the Occurrence of Ethereal Sulphates in the Plant, by P. Haas.—"Fumed" Oak and Natural Brown Oak, by C. K. Tinkler.—A Method for the Preparation and Recrystallisation of Oxyhæmoglobin, by H. W. Dudley and C. L. Evans.—Pure oxyhæmoglobin, being less soluble than reduced hæmoglobin, is precipitated in crystals when a strong solution of reduced hæmoglobin is treated with oxygen.—Feeding experiments in connexion with Vitamins A and B: (1) The Value of Steam-distilled Palm Kernel Oil as a Control Fat. (2) Wheat Bran as a Source of Vitamins A and B, by A. D. Stammers. Steam-distilled palm-kernel oil forms a convenient vitamin-free fat for diet experiments. Bran is shown to contain vitamin A sufficient to produce growth as good as that obtained on a butter-fat diet, and there is no reason to believe that the antineuritic properties of bran are inadequate.—The Behaviour of Pectin towards Alkalis and Pectase, by F. Tutin.—Further Observations on the Digestion of Fibrin and Caseinogen by Trypsin, by E. S. Edie. Comparisons of the power of pancreatic extracts to clot milk and to digest caseinogen and fibrin under various conditions of acidity, age, &c., suggest that these actions are brought about by distinct enzymes or at least by different groups of one complex enzyme molecule.—A Note on the Question of the Identity of Gastric Rennin and Pepsin, by E. S. Edie. The gastric rennin appears to be a different enzyme from pepsin. The newly-born rabbit's stomach contains rennin but not pepsin, the adult stomach gives pepsin but not rennin.—The Estimation of Non-Protein Nitrogen in Blood by a Micro-Kjeldahl Method, by E. L. Kennaway. The technique is adapted for clinical work.—Denitrification as a Means of Sewage Purification, by E. A. Cooper. It is shown by experiment that considerable economy can be introduced in sewage purification by mixing part of the sedimentation tank liquor with the filter effluent, and thus employing the nitrate present in the latter for destruction of the more readily fermentable material in the former.—A Method of Protein Removal from Body Fluids for the Purpose of Simultaneous Determination of Many Constituents, by G. Mukai. The proteins are mainly precipitated by means of a hot aqueous sodium acetate-acetic acid mixture, any small residue being adsorbed by talcum powder. Chlorine, non-protein nitrogen, and sugar can be estimated in the filtrate.—The Anti-Scorbutic Properties of Concentrated Fruit Juices, Part IV., by A. Harden and R. Robison. By storing evaporated orange-juice at a temperature of 29° C. for 14 months 50 per cent. of its anti-scorbutic power was destroyed.—Studies on Gelatin, Part I.: The Dynamics of the Formation of Gelatin from Ossein, by A. B. Manning and S. B. Schryver.—The Formation of Vitamin A in Living Plant Tissues, by K. H. Coward and J. C. Drummond. Dried seeds in general contain but little vitamin A, and the amount does not increase during germination. The vitamin is synthesised in green leaves and chlorophyll-containing algæ, but not in etiolated seedlings and in plants devoid of chlorophyll. The active substance is not associated with proteins but is extracted with the fat.—Researches on Vitamin A. VII. Notes on the Factors Influencing the Value of Milk and Butter as Sources of Vitamin A, by J. C. Drummond, K. H. Coward, and A. F. Watson. The content of milk in vitamin A varies considerably as the result of variations in the diet of the cow. Colostrum is richer in the vitamin than milk, and milk is richer than the butter made from the milk. Processes in the manufacture of butter which involve exposure to air at high temperatures lead to destruction of the A factor. The vitamin is, however, not affected by storage unless oxidative changes take place. Production of free fatty acid does not destroy the vitamin if oxidation be prevented.—On the Theory of Gels, by S. C. Bradford.

BRITISH JOURNAL OF OPHTHALMOLOGY. October and November, 1921.—In the October number is a report of the lecture delivered to the Oxford Ophthalmological Congress last July by E. E. Maddox on Heterophoria.—S. Miyashita and Y. Nisyake, from the ophthalmic department of the Medical College of Osaka, contribute an article on a rare pathological condition — Retinal Degeneration with Multiple Aneurysms—of which only some 13 cases have been previously recorded.—A. S. Percival writes on Decentration and Oblique Cylinders.

In the November number the subject of Retinal Pulsation is discussed by Colonel R. H. Elliot in a paper of considerable interest. His explanation rests on the theory that the intra-ocular blood pressure varies directly with the amount of fluid in the eye, a theory contested by Thomson Henderson and others, who believe that the scleral envelope is not distensible, and that the amount of fluid in the eye is constant. According to Elliot the arterial pulse is seen whenever the intra-ocular pressure passes the pressure in the arteries during the period of diastole, but is lower than the latter during the systolic period. It is always of pathological significance but can be produced artificially by digital pressure. If, when an artificial pulse has been produced in this way the pressure of the finger is gradually increased, the pulsation ceases again as the intraocular pressure becomes greater than the systolic arterial pressure, but this experiment is justly criticised as being not without danger to the patient. The phenomenon of the venous pulse is of a totally different nature. It is physiological but only to be observed in a certain proportion of subjects, and the pulse is not nearly so marked as the arterial pulse when that exists. The cause of the venous pulse is that in the cardiac cycle the systolic arterial pressure coincides with the period of lowest pressure in the veins; assuming the time between the heart beats to be eight-tenths of a second, and that in the fifth tenth we have a maximum pressure within the veins owing to the auricular systole, in the seventh tenth the ventricular systole will cause a maximum pressure within the arteries at a moment when the venous pressure is at its minimum. Hence the pulse. Colonel Elliot goes on to discuss the varying effects of digital pressure on the venous pulse, its relation to glaucoma and kindred problems. He also contributes an article on the haloes of glaucoma.—An article by W. H. Simpson on Safety in Ophthalmic Operations gives the details of the precautions adopted at Moorfields (at which hospital he was senior house surgeon) before and during cataract operations.

Bristol General Hospital. Dr. Clarke pointed out that as the main function of the kidney was to excrete urea, tests of its efficiency should be tests of excretion of urea rather than of other bodies. Clinical experience, as well as experiment, had shown that the power to excrete urea was, like other vital functions, carried on in health with a large margin of reserve tissue not actually in use. It was the gradual destruction of this margin by disease that the diagnostician aimed to discover. The usual clinical symptoms were not produced till the kidney had lost two-thirds of its urea-excreting tissue, and the object of renal efficiency tests was to anticipate the symptoms in demonstrating the encroachments of disease. Dr. Clarke mentioned three methods of estimating the urea outflow: the two-hour renal test, the urea-concentration test, and the estimation of blood-urea. By means of charts Dr. Clarke demonstrated the close parallelism between the curve of fluid outflow, as demonstrated by the two-hour renal test, and the output of urea; so close was this relationship that he had learnt to regard the two-hour renal test as the most valuable of the simple means of watching the renal functions. Dr. Clarke said that it was possible by means of this test and particularly by noting the ratio between the diurnal and the nocturnal output of urine, to detect earlier phases of disease than by the urea-concentration test. He alluded to the phenolsulphonephthalein test, particularly in relation to the estimation of the efficiency of the "surgical" kidney, and said that though it was a rough index of efficiency in such cases, the estimation of blood-urea afforded more reliable data. With regard to blood-urea estimations in diffuse nephritis, Dr. Clarke had found that whereas in chronic nephritis there was usually evidence of considerable nitrogen retention, in the acute and subacute varieties this was usually less marked. A rising percentage of urea in the blood in any such case was, according to general agreement, of grave import. In circulatory failure, unaccompanied by primary renal disease, there might be a considerable rise in the percentage of urea in the blood.

Dr. J. O. Symes then gave an account of his experience of renal efficiency tests in five years' private and hospital practice. The blood-urea test was accurate and reliable, but too laborious and complex for routine use. The two-hourly renal test was the one he had found to be most useful in practice, because it combined simplicity with accuracy. The urea-concentration test was not ideal for private practice, because of the difficulty of controlling the dietetic and other conditions under which the test was made. Dr. Symes had found renal efficiency tests of value in diagnosis; for example, in cases of arterio-sclerotic kidney the grade of efficiency was relatively high, while in contracted granular kidney it was low. From a prognostic point of view Dr. Symes found the blood-urea estimation of most value; this was also useful in treatment, since a high blood-urea figure indicated a reduction of the nitrogenous elements in the diet.

The Laboratory Point of View.

Dr. Geoffrey Hadfield gave an account of the tests from the laboratory point of view, speaking of them from three aspects: the possibility of simplification, the correlation of test results with post-mortem findings, and the localisation of intra-renal disease (for example, the distinction between glomerular and tubal lesions). In particular he described means of controlling the hypobromite method of estimating the urea in urine, and the urease method of estimating urea in blood and in cerebro-spinal fluid. There were, he said, wide divergences between the results of these tests and the anatomical changes found post mortem, due in part to the element of circulatory failure, local as well as general, which entered into a majority of renal deaths, in part to the capacity for compensating changes, physiological and anatomical, which the diseased kidney displays; due also to the fact that in most diseased kidneys the changes are local and not evenly distributed. Some margin had also to be allowed for autolysis of the renal tubules ensuing after death. Dr. Hadfield's remarks were illustrated by a series of lantern-slides from microphotographs, among them specimens taken from a living kidney which had been treated surgically by decapsulation.

Dr. A. T. Todd alluded to the diastase test, also to certain French methods of estimating the chloride output and the diurnal variations in specific gravity.—Dr. J. R. Charles criticised the prognostic application of renal efficiency tests on the ground that at best they only foretold the approach of uræmia, a mode of breakdown responsible for only a small percentage of renal deaths.—Dr. O. C. M. Davis described certain inaccuracies of the hypobromite estimation of urea in urine.—Mr. J. Lacy Firth, speaking from the surgical point of view, supported the indigo-carmine and ureteral catheter methods, particularly for cases where it was desired to measure the relative efficiency of the two kidneys.—Dr. J. A. Nixon asked whether the tests did not tend to the formation of too favourable a prognosis.—Drs. Clarke, Symes, and Hadfield replied.

NORWICH MEDICO-CHIRURGICAL SOCIETY.

At the opening meeting of this Society, held at the Norfolk and Norwich Hospital, the chair was taken by the newly-elected President, Dr. William Wyllys, of Great Yarmouth.

Dr. A. F. Hurst (London) delivered an address on

Psycho-therapy,

illustrated by kinematograph pictures. He emphasised the benefit derived by patients suffering from organic disease of the nervous system, through the relief and cure by psycho-therapy of the functional element always associated therewith. He laid great stress on the following methods: (1) Explanation, after due physical examination and questioning; (2) persuasion; and (3) re-education, which should be carried out in a short space of time, and not allowed to drift into a matter of weeks and months. By this system Dr. Hurst said he had cured ordinary fainting, vomiting of pregnancy, flatulence, chronic constipation, mucous colitis, and chronic rheumatoid arthritis. His address was followed by an interesting discussion.

A Clinical Meeting was held on Nov. 1st, when the following cases and specimens were shown:—

Dr. G. P. C. Claridge showed a woman and a child suffering from lupus of the face. Both had been treated by various ointments and other applications with indifferent results, but had greatly improved under injections of tuberculin. He used the old T.R. and thought it was most important to push it. He began with an initial dose of 1/50,000 mg. and the woman was now having a dosage of 1 mg. and the child 1/3000 mg.

Dr. A. J. Cleveland showed a case of a young woman with definite symptoms of disseminated sclerosis, following an attack of encephalitis lethargica. He thought there was a distinct connexion between the two diseases.—Dr. V. H. Blake recalled a very similar case which he had diagnosed as encephalitis lethargica, but which was considered by a consultant to be one of disseminated sclerosis. The patient, however, ultimately recovered—a point in favour of Dr. Blake's diagnosis.

Dr. Cleveland also showed a man, aged 38, with general tremors, and a boy, aged 13, with hysterical paraplegia following on an attack of tonsillitis and rheumatism. The boy firmly believed that he could not walk, although there was no real paralysis, and the reflexes were normal.

Mr. Cecil Muriel showed a case of total ophthalmoplegia of the left eye in a young woman who had been under his care at the Eye Infirmary. The attack began with headache, and two weeks later diplopia and ptosis developed. There was then complete paralysis of the third, fourth, and sixth cranial nerves—in Mr. Muriel's experience a very rare condition. There was a positive Wassermann reaction, but no history of syphilis could be obtained, although the patient had a child a few years ago who had congenital syphilis. She had been treated by injections of novarsenobillon, as well as by mercury and iodides. There was no appreciable improvement for six or seven weeks, but Mr. Muriel said that she could now raise the lid slightly and could turn the eyeball inwards, though unable to move it outwards at all.

Mr. T. W. Hancock brought forward two cases. The first was a boy of 14, suffering from fragilitas ossium. The history was that both arms and both legs were fractured at birth, whether in utero or during delivery was not clear. The bones were so brittle that the very slightest injury served to break them; the right thigh had been fractured eight times, the left thigh once, and the clavicle once. The fractures always united well. The boy was very stunted in growth, but his intelligence was excellent, and his pituitary functions normal. Radiograms of the fractures were exhibited. Mr. Hancock's second case was brought for diagnosis. It was a small girl with a new growth at the base of the skull, over the frontal bone, which pressed down on the eyeballs and seemed to be increasing in size. Quite recently swellings had developed in both wrists.—Various opinions were expressed by members as to the probable pathology of these tumours, but no definite conclusion was reached.

Dr. E. B. Hinde showed a case of hemianopia, with fits of the nature of Jacksonian epilepsy.

The following specimens were shown:—1. Mr. A. J. Blaxland: Volvulus of the sigmoid, removed from a man of 55. 2. Dr. Hinde: Three placentæ—(a) Placenta succenturiata; (b) velamentous insertion of cord; (c) twin pregnancy with hydramnios. 3. Dr. A. Crook: Microscopical section of a placenta in a case of toxæmic vomiting. 4. Dr. S. H. Long: Sarcoma of liver from an infant of nine weeks. 5. Mr. E. W. Everett: Enlarged gall-bladder, with hard thickened coats like tough leather.

print in full at the opening of this issue, Dr. W. A. POTTS, speaking from his experience as psychological expert to the Birmingham Justices, states that nearly all the so-called moral imbeciles he had examined were mentally defective. There is, he roundly asserts, no criminal type, and recent investigations have even thrown doubt on the inheritance of mental defect as such. He spoke of psychical as distinct from physical inheritance. A child may inherit the tendency to evade rather than face difficulties, and he placed the critical period in such a child's history very early indeed. Nearly all the young Birmingham delinquents were on the wrong path, he said, at ten years of age and even earlier. The alleged first offender is not, in Dr. POTTS's view, an innocent little person to be dismissed with a caution, but an individual on the wrong path whose case requires thorough expert examination.

We are unfortunately too ignorant at present to deal with many of these delinquents other than by punitive detention, but what is really most necessary now is an inquiry into their mental life. There will probably be no doubt in the minds of those who have experience of the class, that the case described in considerable detail by Dr. NORWOOD EAST in our last issue is truly a case of moral imbecility; indeed, in its features of persistent crime from an early age in spite of all refining and reforming influence and of repeated punishment, in the apparently complete absence of any sense of morality and social responsibility, and in the lack of wisdom to see the personal disadvantages resulting from such misconduct, it is a very characteristic case of this condition. With regard to the boy HAROLD JONES, who, on his own confession deliberately murdered two young girls in the most callous manner, we are, it is true, without any expert evidence as to his mental state, but this case also comes within the same category. The condition of moral imbecility is one of very great scientific interest, especially in regard to its psychology and ætiology. Sound authorities regard it as due to a definite defect of mind of such a nature that the sufferer is permanently incapable of controlling his conduct so as to conform to the legal and moral standards of society. Then there arises the interesting question of the cause of such defect. In many instances it is likely that this is the same as that of ordinary mental defect, the imperfection, however, being chiefly or entirely incident upon the inhibitory functions. But it is possible that some of these cases may stand upon a quite different footing, and that in them the defect may be analogous to the "sports" and "freaks" which occur in plants and animals, rather than due to a pathological condition of the germ plasm. However this may be, it is recognised that true moral imbecility is incurable, a thing which entails social consequences of such importance as completely to overshadow any academic considerations. Perhaps the fact which strikes us most forcibly is that serious, indeed alarming, danger to the general public must arise from the freedom of these persons, and in this connexion it is necessary to remember that neither HAROLD JONES, nor the persistent criminal, whose life Dr. EAST has sketched for us, are unique cases; they are merely representative of a not inconsiderable class. It is obvious that the public safety demands that the condition which makes such conduct possible should be diagnosed, and that persons suffering from it should be placed under suitable care at the earliest possible moment.

Diagnosis is a matter of great difficulty; there are several conditions closely resembling moral imbecility which are curable under appropriate treatment, and it is not impertinent to ask whether the practitioner invariably possesses the requisite knowledge of psychological medicine, and particularly of mental deficiency, to make such a diagnosis. We are of the opinion that he does not, and for this reason we welcome the increased facilities which are now being afforded in London and elsewhere for instruction in this subject. A further advance might be made. The subject of mental deficiency is one of such medical and social importance that the time has arrived when the establishment of university chairs might be considered. There seems to be a need for the mental examination not only of all young persons charged with serious crime, but also of all persons repeatedly coming before the courts. If adequate arrangements existed for such examinations, it should surely be possible to detect sufferers from moral and other forms of mental deficiency before they were able to commit an alarming series of crimes.

Pragmatism in Medicine.

ONE of the most significant features of the progress of medicine in recent years has been the enthusiasm with which laboratory methods have been brought into use in the investigation of sick people. That a large and expensive book like Prof. J. J. R. MACLEOD's "Physiology and Biochemistry in Modern Medicine" should quickly reach its third edition indicates a definite change of attitude among our clinicians. The University of Sheffield now detaches members of its physiological staff to work and give instruction at the hospitals with which it is associated. And it has lately been announced that the Clinical Society of Manchester will no longer devote its meetings to the discussion of unusual and difficult cases, but that the demonstration of new methods of laboratory investigation and diagnosis will now form part of the regular programme.

That all this and other changes along similar lines which are everywhere taking place is for good no one can doubt. The time has quite gone by when it can be argued, as it used to be, that it is bad education to teach a student to use agglutination tests in the diagnosis of obscure fevers because they deprive him of the improving gymnastic of nicely balancing the variable signs which he can sometimes ascertain by methods of more respectable antiquity. No one believes that clinical sense can be replaced by laboratory manœuvres, but neither does anyone of sense any longer look askance at the help to diagnosis which emerges from research. It has been said that a scientific thesis may be taken to be "true" if it is productive of fresh knowledge. And on this pragmatical basis the proposition that the secrets of medicine will be revealed along the lines of present activities, so diverse and so keen, will receive general assent. But those who are more reflective than enthusiastic may feel some certainty that there are a good many problems in clinical medicine that have to be solved by clinical methods. The attractiveness of all new procedures is obvious and the desire to see good in them is natural. Just as experimental work in the laboratory is of its essence simpler and easier than any kind of clinical inquiry of equal seriousness, so clinical investigation of a laboratory kind is simpler than that to which methods of precision cannot be applied. This must necessarily be so, because the whole object of the experimental method is so arbitrarily to restrict and simplify the diseases and is based on the author's own experience of the jaw-neck syndrome, the presence of which he regards as of cardinal importance. His views on this point are set forth in an original article on p. 1097. More might reasonably have been said on the influence of environment, climate, and suggestion in the last chapter, for, as the author points out, the spa physician undoubtedly finds that environment greatly facilitates the use of the suggestive treatment, which is consciously or unconsciously employed by every medical man every day of his life. Dr. Herbert's book appears at an opportune time and is a welcome addition to the literature of climatic therapy.

PHARMACY.

Pharmacopœia of the University College Hospital. Edited by CHARLES H. HAMPSHIRE, B.Sc. Lond., F.I.C., Ph.C., Pharmacist and Teacher of Pharmacy to the Hospital. London: John Bale, Sons and Danielsson, Ltd. 1921. Pp. 96. 4s.

THIS hospital pharmacopœia contains a list of the special pharmaceutical preparations used in the University College Hospital. Twenty-five new formulæ have been added, five have been deleted, and a children's section has been formed. The book includes much useful miscellaneous information upon diet, urine analysis, the blood, staining of bacteria, treatment of poisoning, &c.; many of these sections have been revised and partly rewritten by Dr. G. W. Goodhart, clinical pathologist to the hospital.

BLOOD DISEASES.

Polycythæmia, Erythrocytosis and Erythræmia (Vaquez-Osler Disease). By F. PARKES WEBER, M.A., M.D., F.R.C.P. London: H. K. Lewis and Co., Ltd. 1921. Pp. 148. 21s.

IN this monograph Dr. Parkes Weber reviews the subject of polycythæmia in all its bearings. The author's experience of the numerous and somewhat uncommon clinical conditions which he describes, his extensive knowledge of the literature, and his personal acquaintance with many of the cases, both published and unpublished, of other observers make the work an important contribution to the knowledge of polycythæmia, and a valuable book of reference.

Polycythæmia is defined as a condition of the blood in which the number of red blood corpuscles is decidedly above the average. It occurs in two forms; in one the increase in red blood corpuscles is relative and due to a concentration of the blood, in the other it is absolute (true) and there is an actual increase in the total number of red corpuscles in the body. Two forms of absolute polycythæmia are recognised—namely, erythrocytosis and erythræmia. Erythrocytosis is analogous to leucocytosis and results from an increased activity of the erythroblastic tissues in response to the call made by such conditions as living at high altitudes, chronic cardiac and pulmonary disease. Erythræmia is analogous to leukæmia, and is described as due to an excessive erythroblastic activity of the bone-marrow, which appears to be the primary morbid factor in the condition.

The characters of the blood and the state of the bone-marrow in absolute polycythæmia, as also its ætiology, are described in Part 1. Erythræmia in all its aspects is described in Part 2, while a valuable appendix gives an account of the post-mortem findings in cases of erythræmia and splenomegalic polycythæmia; a second appendix contains a record of remarkable or obscure cases of polycythæmia. Part 3 contains a short account of a number of hitherto unpublished cases, and a considerable body of literature, mostly issued since 1908. Scattered through the several records in this chapter are many discriminating comments which throw light on the relation to polycythæmia of such conditions as polycythæmia hypertonica, "Ayerza's disease," syphilitic arteriosclerosis of the pulmonary arteries, described by Warthin, phlebitis spleno-portalis, and thromboangiitis obliterans of Leo Buerger. Taken as a whole, the cases detailed in this chapter emphasise the importance of chronic arterial disease in its relation to secondary polycythæmia; at the same time a careful study of its contents makes the reader realise that, though splenomegalic polycythæmia may be easily recognised as a clinical entity, the diagnosis of erythræmia requires uncommon knowledge and care. In a final chapter Dr. Parkes Weber discusses some aspects of his main thesis that erythræmia is a primary disease of the bone-marrow.

THE PROSPECTIVE MOTHER.

Second edition. By J. MORRIS SLEMONS, M.D., Associate Professor of Obstetrics, Johns Hopkins University. London and New York: D. Appleton and Co. 1921. Pp. 343. 9s.

THIS book, the first edition of which appeared in 1912, is described by the author as a "handbook for women during pregnancy," and appears admirably to fulfil this function. The 12 chapters cover most of the essential points in the intelligent care of the pregnant woman as regards general hygienic measures, both antenatal and postnatal, the author striking a happy medium between the very elementary teaching often to be found in similar handbooks, and the more technical instruction proper for the use of students and midwives. A glossary is provided for the explanation of the few technical words the use of which was unavoidable. The chapters on the anatomical and physiological changes involved in the development of ovum and embryo are adequate and clearly written, and should prove interesting to prospective mothers.

While there is nothing outstandingly new or original in the volume, the second edition is well abreast of the more modern teaching, especially as regards infant feeding. We note that the author is doubtful as to the value of "twilight sleep" anæsthesia which, in his opinion, has not stood the test of a fair trial. The book may cordially be recommended to young wives and mothers.

ENCYCLOPÆDIA MEDICA.

Second edition. Under the general editorship of J. W. BALLANTYNE, M.D., C.M., F.R.C.P. Edin. Vol. VII., Intestine to Labour. London and Edinburgh: W. Green and Son. 1921. Pp. 611.

THE most important section in this volume is that dealing with labour, occupying as it does some 260 pages. It consists of a series of sections contributed by different writers dealing with all the conditions of normal and abnormal labour. The articles contain a good account of the subject, and are of particular interest at the present time; they are largely conservative in their teaching and are representative of all that is best in the Edinburgh school of obstetrics. A great deal of the matter contributed by the original authors in the first edition has been left unaltered. For example, that dealing with Precipitate and Prolonged Labour by the late Dr. Herman has, it is true, been revised by Dr. R. W. Johnstone, but it still retains all the essentials of the original. We need hardly say that it is admirable in its conception and treatment of this important branch of midwifery, particularly that part dealing with primary and secondary uterine inertia and obstructed labour, the "very key-stone," as the late Dr. Braxton Hicks used to say, of sound practice in midwifery.

Dr. Haultain deals with the Physiology of Labour and the operation of Version; Dr. Ballantyne with the Stages of Labour, the Management of Labour, Postpartum Hæmorrhage, Accouchement Forcé, Symphysiotomy and Pubiotomy; Dr. W. E. Fothergill with Faults in the Passenger and the Induction of Premature Labour; while other articles are contributed by Dr. T. W. Eden, Dr. Amand Routh, Dr. W. R. Dakin, Dr. Murdoch Cameron, the late Dr. W. Stephenson, and the late Sir Alexander Simpson. The teaching, on the whole, is sound, as would be anticipated in view of the reputation of the contributors. The advice to induce premature labour by the old-fashioned manual dilatation rather than by bougies or a hydrostatic pounds. The fact implies a very generous measure of confidence in the voluntary hospital system on the part of the public of this country, and this confidence it will be the special concern of the County Committees to foster by judicious spending.

MALARIAL PREVALENCE IN TEMPERATE CLIMATES.

THE effect of meteorological conditions on the incidence and distribution of malaria was hard to interpret before the discovery of an intermediate host. Writing in 1889 on the Geographical Distribution of Some Tropical Diseases, Dr. R. W. Felkin remarked that the malarial poison was ponderable and was disseminated by wind and water with a special relation to mean annual temperature. The relation to subsoil water and the amount of organic matter in the soil were noted as unexplained. Much of the difficulty has been cleared up by a study of the natural history of the mosquito. but discrepancies remain.

Malaria is more frequent in Bulgaria since the war, because of the 400,000 infected soldiers who came home uncured after their malarial attacks. still *carrying gametes* in their blood. A severe epidemic was expected in 1919 to follow their return, but, on the contrary, the cases were unusually few; 1920, however, was the worst year for 20 years. In the spring of 1919, the Bulgarian Government, anticipating a large increase of cases. set up a malaria prevention inspectorate, on the work of which Dr. S. Konsuloff reports in a recent paper.[1] In the different districts of Bulgaria the prevalence of malaria in any year varies with the meteorology of the seasons, through their influence on the breeding of anophelidæ. In the plains the most numerous mosquito is *A. maculipennis;* in the N.E. and in the rice-fields *A. pseudopictus;* in *the* S.W. in *the hills*, *A. superpictus*, very plentiful around the Struma valley, especially in ravines and small streams, in small pools full of algæ, and in pools, however shallow, amongst the pebbles on either side of the streams, but it is not found in the muddy-bottomed pools of the plains; these maculipennis chiefly affects, though it is also found in the gravelly pools with superpictus, which, however, requires only very small pools to breed in. Superpictus does not shun houses altogether, neither does it crowd into them like maculipennis. Superpictus carries malaria to almost waterless villages to which all water has to be carried, as it can breed in the tiniest puddles left in ravines and broken ground; so in Crete, and in Greece too, the most malarious districts are not those with obvious marshes. It will be seen from the Bulgarian work, here summarised, that the personal details of the mosquito's life are a determining factor in the vagaries of malarial prevalence. The annual course of mosquito development begins about April when the females which have hibernated commence to lay their eggs. As the temperature is low these develop slowly (not at all below 53° F., only slowly up to 60° F.) and the mosquitoes of the first brood appear in the end of May or the beginning of June. Twenty days thereafter the new females begin to lay, and the second brood appears in July, the third arrives from the middle of August to the middle of September; there may be a fourth but the temperature is by this time too low to permit the development of the malarial parasite. The third brood often fails because the streams in July have dried up and there is no water for the larvæ—this, of course, does not apply to the rice-fields, where the water level is artificially maintained. It can now be explained why there was so little malaria in 1919. That spring was exceptionally cold, development was consequently slow; the females, when they did come out, were too chilled to begin feeding at once, so their eggs were laid, not in April but in June. Thus one brood was lost. The next brood was developing through the summer, which in this year was unusually hot, and the drought, drying up the pools, destroyed it. Everyone in Bulgaria noticed in 1919 how few mosquitoes there were and how few cases of malaria. Rain-storms affect superpictus in the higher ground. As there are no forests, the rains at once flood the ravines, wash the larvæ out of their small pools and destroy them, and if these spates are repeated within a month the next developing brood is wiped out. That is what happened in 1919. On April 25th came rain, so heavy that a bridge in the Struma valley was washed away, and another rain-storm followed on May 7th. Therefore in the superpictus area, too, there was little malaria that year.

As we now understand better, in the light of these observations, the natural history of the mosquito, it may be in some degree possible another time to forecast in June the extent of the epidemic that will come in the following summer. A cold spring delays development of all mosquitoes and lessens malaria. Heavy rains in spring decrease superpictus, but rains in summer increase maculipennis, decreasing, respectively, and increasing malaria in their districts. These observations confirm those of Dr. C. M. Wenyon for Salonika, recorded in THE LANCET of Oct. 1st (p. 710).

AVIRULENT TUBERCLE BACILLI.

THE variation in virulence of tubercle bacilli under changing environment is of the utmost practical importance. In the *Annales de l'Institut Pasteur* for September. Calmette, Boquet, and Nègre give an account of experiments conducted with bovine bacilli grown for a long period upon potato in the presence of ox bile. This medium produces a modification in the virulence of the bacilli, which in other respects remain unchanged. The loss of virulence seems somewhat selective, and it is rather surprising to find that it is most marked in the case of the guinea-pig, an animal which is normally extremely susceptible. The bacilli still retain the power of provoking sharp reactions, and of producing typical tuberculous lesions in the rabbit when inoculated in sufficiently large doses. The guinea-pig appears able to resist very large doses of these bacilli, whatever may be the route by which they are given. A local inflammatory lesion is produced by the larger doses, which may break down and become evacuated; subsequently, healing takes place and no generalised tuberculosis is produced. When introduced intravascularly, or into the alimentary tract, after a latent period of some 20 days general symptoms appear, with swelling of the lymphatic glands; but the illness is recovered from. When the animals are killed during the acute period of this illness—and this was the case in many experiments—the bacilli are found in various organs without the characteristic lesions of tuberculosis, phagocytosis of the organisms by large mononuclear cells instead being a prominent feature. The injection of the modified bacilli into an animal suffering from spontaneous chronic tuberculosis resulted in a reaction akin to that produced by tuberculin, but developing more slowly and persisting for a greater length of time.

Attempts were made to protect guinea-pigs from virulent bovine bacilli by inoculation with the modified strain. Where such immunising injections were given subcutaneously no apparent protection was conferred, but where a single dose of the modified organisms was injected intracardially, and infection with a virulent strain attempted a month later, the results were of considerable interest. Whereas control animals succumbed regularly, with large caseous glands and generalised tuberculosis, the immunised animals, at the end of three months and a half, were alive and apparently in good health. When killed and examined no generalised disease was found, but the glands in the region of the path of infection were found to be enlarged and, on section, showed a thickened capsule with a clear, serous, fluid content, containing but few leucocytes and only occasional bacilli. The authors are guarded about the interpretation of these results, which are too recent to be anything but provisional,

THE LANCET.

LONDON: SATURDAY, NOVEMBER 26, 1921.

Cancer Research.

THE seventh scientific report[1] of the Imperial Cancer Research Fund, which has just been published, contains seven papers, four of which are reprints while three appear now for the first time. Apart from their intrinsic value as positive contributions to our knowledge of cancer, these papers have a further interest as marking what are practically fresh lines of investigation in the experimental study of this disease. Modern cancer research may be said to date from the recognition of the fact that spontaneous tumours in animals can be successfully transplanted into other animals of the same species, and propagated indefinitely in successive generations. Previously it had only been possible to study sporadic tumours as they occurred in human beings or occasionally in animals, and histology was almost the only field for investigation; but with the advent of the transplantable tumour of the laboratory animal it became practicable to undertake purposeful investigations under properly controlled experimental conditions. At first, objections were raised to this experimental study of cancer on the grounds that tumours in animals were not true neoplasms and bore no real relationship to the malignant growths which occur in man. Much careful and laborious work was necessary, as may be seen from a glance at the first three or four reports of the Fund, before contemporary die-hards were convinced that cancer is ubiquitous in the animal kingdom. An echo of this dispute, at one time acute, is seen in the paper demonstrating lymphatic dissemination in spontaneous tumours of the mouse, which appears in the present report

Partly because the trend of scientific medicine was strongly towards the study of immunity, partly because of questions raised by some of the earliest experiments in transplantation, interest was focussed from the first on the natural and acquired resistance of animals to the inoculation of tumour tissue. This field has been thoroughly worked, almost exhausted, in fact, and a vast amount of information, much of it of real value to the student of human pathology, has been accumulated; nevertheless, the fundamental problems seem no nearer solution and it is clear that research must proceed in other directions. An important new method of investigation which is rich in promise has, indeed, been developed during the last few years. In 1915 two Japanese workers reported the production of cancer in the skin of rabbits in response to the application of tar. Similar results were obtained in mice by Japanese and Danish investigators, and there is no doubt that a method is now available of producing, with a considerable degree of certainty, malignant growths of epithelium under conditions which are ideal for purposes of observation and experiment. In the laboratories of the Imperial Cancer Research Fund the study of tar cancer in mice has been in progress for some 18 months, and in the current report the director publishes the results of his preliminary observations. 190 mice were painted on the back with coal tar once or twice a week, and of them 23 developed true cancer of the area painted. Inasmuch as the death-rate from intercurrent disease was considerable—the number of survivors was only about half after four months—and the first definitely malignant tumour developed only after about 17 weeks' tarring, the development of true cancer in 23 mice indicates a fairly high percentage of successful results. The malignancy of the tumours was established by their histology, by the fact that they continued to grow after the application of the tar was discontinued, and by successful autoplastic transplantation. This consists in the removal of a small fragment of the tumour and its inoculation into the subcutaneous tissues of the animal in some part well removed from the primary tumour. This method of autoplastic transplantation corresponds practically to an artificial metastasis, and successful autoplasts are by far the surest tests for malignancy; the test can be carried out long before local infiltration or spontaneous dissemination reveals the true nature of the growth, and it is valuable in differentiating tumours which, histologically, are indistinguishable from innocent forms. It has been demonstrated in these experiments that the malignant change occurs in small isolated groups of epithelial cells and not diffusely over the whole of the painted area. Further, some animals seem more susceptible to the tar than others, and develop tumours after a much shorter application. Thus, in this experiment the earliest carcinoma developed in the eighteenth week, and the latest only after 52 weeks' treatment; and it has also been noted that in the earlier tumours the histology closely approaches the normal, whereas in those developing later, loss of differentiation may be extreme.

Other papers in the report deal with investigations into the physiological processes of normal and malignant cells. These experiments are obviously of fundamental importance; it is too soon as yet to theorise on their application to neoplastic conditions, but this is without doubt a line of research from which much may be expected. Finally there is a long histological paper on the Golgi apparatus of transplantable tumour cells. This again amounts to a preliminary communication on a very laborious research, but it is the morphological counterpart to the physiological investigations to which we have referred. Structure and function are inseparable; the one must vary with the other, and it is by an extensive study of cellular physiology and morphology that we may best hope to discover those elusive properties of malignant cells which distinguish them from their innocent forbears. This is the first scientific report of the Imperial Cancer Research Fund published since 1912, if we except the sixth report, which dealt with the work of members of the staff and had more to do with war pathology than with cancer research. And it is encouraging to find the subject of all others in pathology which is regarded by the majority as almost insoluble being tackled with freshness of outlook and undiminished enthusiasm.

* * *

Moral Imbecility.

AT the first sessional meeting of the Oxford Medical Society Dr. J. M. MACPHAIL brought forward a case of moral imbecility in a stalwart-looking man who had served three and a half years in the army and showed little outward sign of defect, but in whom application of the point-scale method of examination was successful in demonstrating a level of intelligence below the normal standard. In his lecture to teachers, which we the sort of universal compliance which aims at popularity and, as a rule, misses it. It could have been no easy matter for a man of advancing middle age to enter into the ways of life and modes of thinking of a University to which he was himself a stranger, particularly when that University and its colleges possessed over 600 years of tradition. Marsh managed admirably. His birth made him a persona grata with the College tenants, especially as most of the property of Downing College is agricultural and lies in East Anglia. His familiarity with men and manners, acquired in the conduct of a first-class London practice, made him an acquisition in the social circles of the University. And his skill at his own métier was beyond question. Among his other duties he took a deep interest in the Boy Scout movement, being the first Commissioner of Scouts in Cambridge, and on the outbreak of war he threw himself vigorously into all the University movements to help his sorely tried country. He died from a heart attack at the age of 76, leaving behind him the memory of a man who always did his best; and he would have desired no more fulsome epitaph.

PSEUDOXANTHOMA ELASTICUM.

ACCORDING to Dr. Binford Throne and Dr. Herman Goodman,[1] of the New York Skin and Cancer Hospital, who record an illustrative case with a histological report by Dr. D. S. D. Jessup, pseudoxanthoma elasticum, sometimes known as elastoma or nævus elasticus, is one of the rarest dermatoses known, only 15 other examples having been published. The condition was first described by Balzer in 1884, but it was not until 1896 that the name of pseudoxanthoma elasticum was given it by Darier. The ætiology is unknown. It has been variously regarded as a nævus, a form of tumour, and, from association with tuberculosis, as dependent on that disease for its causation. It appears in youthful persons and in adults of both sexes, and more than one member of the family may be affected. Its clinical features are yellowish small papules, individual and confluent or massed into plaques. The skin changes are usually symmetrical, the areas of predilection being the neck and axillæ. The site of the lesions is marked by exaggeration of the normal creases and reduplication of the normal folds. A case, communicated to us, was that of a woman, aged 39, who had had the eruption since the age of 4 years. One of her sisters had also had a similar condition since she was 4 years old and had died of pulmonary tuberculosis at the age of 31. The patient had had a lymph-node incised when she was 18 months old and at the present time showed enlarged mediastinal glands on X ray examination. The clinical diagnosis was confirmed by X ray examination, which showed characteristic clumps of swollen and degenerated elastic fibres with basic degeneration of the collagen fibres in the lower and middle derma. There was little change in the epidermis and pars papillaris of the derma, and there was no involvement of the sweat and sebaceous glands or hair follicles.

MAN-POWER.

THE Man-Power of Australia: its Dependence upon Education, Immigration, and Public Health, was the subject of an address delivered during August to the Millions Club of New South Wales, at Sydney, by Lieut.-Colonel Sir James Barrett, who took as his text the necessity of filling the Australian continent with inhabitants healthy, educated, and highly organised. Recalling his experiences during the war, Sir James Barrett pointed out that the occupation of the army medical officer was one-third treatment of disease, one-third the placing of the partially disabled in suitable occupations, and one-third prevention of disease. There might be established in civil life an analogous system of hospitals for acute cases, convalescent hospitals, and agencies for placing the partially disabled in occupations in which they can still pull their weight. Nothing had been more striking than the care taken in the Imperial army to have men examined by the most eminent British specialists to determine their fitness to fight, and it had occurred to thoughtful men to inquire why the rank and file were not similarly classified for civilian occupations in time of peace. A little more sympathy was required for the disabilities of those at the bottom of the ladder. The organisation and use of expert knowledge were needed for town-planning and provision of playgrounds, and for all the larger aspect of health and hospital problems; and on the mental side it was now recognised that the period from 14 to 18 years was the most important from an educational point of view. Half-time compulsory education was found to be valuable in Japan, France, and England; Australia might find it well to adopt a similar system of civic education with a back-bone of trade interest. Concepts of mental development were altering; in Canada and the U.S.A. forms of manual training were now regarded as an essential part of university education. But even when all the physical and mental wants of a people were attended to, the result might still be a race of healthy, clever scoundrels. Morality was necessary, and since morality was taught more by example than by lessons, every parent should bear continually in mind the motto *Noblesse oblige*. Crude and unformed ideals must be stimulated to develop clear aims in life. The speaker described himself as meeting professional men who said they would have nothing to do with politics or public affairs; to him such men had lost their souls. In a phrase attributed to Huxley: "Every man or woman should be a master in some one department of knowledge, but they should be interested in everything else that takes place in this interesting world."

THE CEREBRO-SPINAL FLUID IN CONGENITAL SYPHILIS.

DR. Otto Tenzer,[1] of the Carolina Children's Hospital in Vienna, remarks that in contrast with the numerous studies of the kind relating to the acquired disease, the literature on the condition of the cerebro-spinal fluid in congenital syphilis is comparatively scanty, while the results obtained by various observers are conflicting. His own investigations comprised the study of four reactions—namely, the Wassermann reaction in the blood serum, the Wassermann reaction in the spinal fluid, cerebrospinal lymphocytosis, and the Nonne-Apelt reaction. In a few instances Pandy's reaction was also performed. It was a remarkable fact that whereas in adults lumbar puncture not infrequently causes symptoms of meningeal irritation in spite of confinement to bed, the only symptoms observed by Dr. Tenzer among 62 lumbar punctures performed were temporary apnœa in an infant and headache and vomiting in an older child. The results of the examination of the cerebro-spinal fluid in 43 cases were as follows: All the reactions were positive in 41·8 per cent., the Wassermann reaction was positive in 32·5 per cent., and lymphocytosis and a positive Wassermann reaction were found in 13·9 per cent. Sixteen of the total number were infants, among whom all the reactions were positive in 62·5 per cent., the Wassermann reaction was positive in 50 per cent., and a positive Nonne reaction and lymphocytosis were found in 31·3 per cent. With one exception, in which the spinal fluid showed lymphocytosis and a positive Wassermann reaction, all the infants presented a well-marked syphilitic eruption. Twenty were older children without nervous symptoms, in whom all the reactions were positive in 15 per cent. and a positive Nonne reaction and lymphocytosis were found in 5 per cent., and seven were older children with nervous symptoms, in whom the Wassermann reaction was positive in 70·1 per cent. and lymphocytosis was found in 20 per cent. Pandy's reaction in the few cases in which it was performed complexities of the real world that they shall be capable of measurement and analysis. It mostly happens that the main difficulties of any problem have been passed when it has been defined and reduced to a form in which it can be subjected to experimental investigation.

[1] Monatsschrift für Kinderheilkunde, October, 1921.

Sir JAMES MACKENZIE tells us that many of the most pressing questions of practical medicine are of the nebulous kind of which the point is at present scarcely visible. No one can answer definitely questions which are not definite; but we can sift the questions and agree upon their meaning as a preliminary to attempting the reply. The natural history of disease is clearly a great field of inquiry at present hardly touched; Dr. W. H. HAMER never fails to remind the laboratory worker that there is something in epidemiology which is beyond and behind bacteriology. In our enthusiasm, therefore, for the facility with which quantitative answers can be obtained with a burette, do not let us forget that there is a good deal of difficult work which wants doing in which its help will be lacking. By a strange confusion of thought, "scientific" work in medicine is often used as synonymous with "laboratory" work. Scientific work is any work done with accuracy and discipline of mind, and this should be as commonly maintained by those who see the sick in their homes or in the wards of hospitals as by those whose careers lie in laboratories.

INFANT MORTALITY IN BOMBAY.

SOME of the attention concentrated on the small but regrettable loss of life which occurred in Bombay at the time of the PRINCE OF WALES'S visit last week might well be given to the appalling loss of infant life constantly occurring in that city. In the quarterly return issued by the Registrar-General the extraordinary infant mortality rate of 630 per 1000 births was recorded for the third quarter of the year, and for the second quarter the return was even worse—viz., 788 per 1000 births. It is only fair to add that the extremely high rates customarily returned by Bombay demand some correction in view of an explanation given by Dr. J. E. SANDILANDS in his annual report as executive health officer. It there appears that the low recorded birth-rate in Bombay, as compared with Madras, is due to the fact that a large number of children born of Bombay mothers are never registered at all or are registered elsewhere, many women going away for their confinement. The Madras recorded rates of 254 and 286 for the same quarters are terrible enough, but may well be near the truth. Calcutta makes no returns, possibly because they would be misleading. We are in great need of accurate figures from India.

TUBERCULOSIS SOCIETY.—The annual meeting will be held on Friday, Dec. 2nd, at 7.30 P.M., at the Caxton Restaurant, Tothill-street, Westminster, and will be followed by a supper in the restaurant. Members intending to be present are asked to forward remittance (4s. inclusive) as early as possible to the hon. secretary, Dr. F. J. C. Blackmore, at 39, Woodland-terrace, Old Charlton, London, S.E. 7. The programme for next session has just been issued. On Jan. 23rd the report of the subcommittee on classification of tuberculosis will be discussed; on Feb. 27th the subject of tuberculosis and X ray work will be considered; March 27th will be devoted to a clinical evening; on April 24th the therapeutics of tuberculosis will form the subject of discussion; and on May 22nd a general discussion on the relationship of dispensaries and other institutions for tuberculosis will take place. On June 26th there will be a provincial meeting, probably at Bristol. Meetings will be held at the Margaret-street Hospital, Margaret-street, Regent-street, London, W., at 7.30 P.M.

Annotations.

"Ne quid nimis."

HOSPITAL FINANCE OUTSIDE LONDON.

THE report on the financial position of 572 voluntary hospitals in England and Wales, excluding London, for the year 1920 follows hard upon the survey of London hospital finance reviewed in our columns last week. The author of this valuable report is director of Hospital Services to the Joint Red Cross Council, and Sir Arthur Stanley in his introduction does no more than justice to Sir Napier Burnett's work when he points out that the figures here set out make it possible for the first time to analyse with precision the sources from which voluntary hospitals derive their income. The annual expenditure per occupied bed averaged in 1920, it seems, £135, as against £107 in 1919. The report suggests that there is every indication of the high-water mark in hospital expenditure having been reached in 1920, and anticipates that the present year will show a considerable reduction in the cost of many hospital commodities. As in London, it is noteworthy that the larger hospitals with 100 or more beds, especially those with medical and nursing schools, are more expensive to run than the smaller hospitals; while the teaching and training of students manifestly exert a stimulating effect upon the standard of diagnosis and treatment, it appears that the actual work done by students does not save any hospital much money. Eleven hospitals replied to a question regarding the fees obtained from medical students: at eight hospitals no fees at all were received and at three others they amounted to an aggregate of £1400 odd. Sir Napier Burnett contrasts this laxity with five Scottish hospitals associated with medical schools at which in 1920 a sum of nearly £11,000 was realised from medical students' fees. The practice has been very different with pupil nurses. Provincial hospital finance differs in one important respect from London experience in obtaining a material source of income from workmen's contributions; these amounted in 1920 to 21 per cent. of the total ordinary income. Whenever a hospital cares to take the trouble, Sir Napier Burnett assures us, to organise this form of collection, it almost invariably meets with a rich reward. One provincial hospital actually received £114 per bed from this source, where another situated in an even more populous district derived but £2 per bed. Contributions from patients themselves produced 9·7 per cent. of the total ordinary income in 1920, exceeding by 2 the percentage of the preceding year; income from public services accounted for 14·4 per cent. of the total ordinary income, a drop of nearly 4 on the percentage of the previous year, simply due to the withdrawal of the War Office capitation grant. The report comments severely upon the paltry £39,000 received by provincial hospitals for services rendered to patients under the National Health Insurance Act. At one large hospital 26 per cent. of out-patients are insured persons making weekly insurance contributions, but this hospital receives no support whatever from insurance funds. Sir Napier Burnett foresees much larger contribution from approved societies to hospitals for services rendered to insured persons. We welcome this report at the present moment for it will be of special value to the County Voluntary Hospital Committees which are just being established. To them it commends the gathering together of provincial voluntary hospitals into federated groups with the object of working out some uniform financial scheme, of establishing some system of coördinated treatment, and of effecting some reduction of expenditure along the lines of coöperative buying. The situation is not desperate for these reasonable remedies have never been tried, while the total moneys received by provincial voluntary hospitals during 1920 actually exceeded the total expenditure by over one million be of extreme value for medical men from overseas and for officers in the Services enjoying study leave, it was held by some that it would not serve the needs of country practitioners. But others at the conference considered that the country practitioners most likely to make use of such post-graduate training would be the ones who could arrange for a prolonged stay away from their practices, while it was a unanimous feeling that a central organisation was necessary with a medical executive officer at its head. A source of income must be obtained, and the movement must be set on a business footing, so that those desirous of post-graduate tuition would be able to get the best advice, and teachers willing to assist should receive some regular remuneration. On these points the meeting was unanimous, and it was resolved to hold another meeting in the near future; this will not be, however, until the Post-Graduate Courses Committee of the B.M.A. have reported to the Council of the Association in February next.

GRATEFUL RECOGNITION.

HOWEVER bravely deformity and disablement has been borne by the sufferers in the war, it rarely has led, in this country at least, to any vocal expression of gratitude to those who spent many of their best years in relieving them. The following testimony from Canada is therefore doubly welcome:—

> *Whereas* we, the amputation cases of the Great War, assembled in Convention at Toronto, this 29th day of September, 1921, on this memorable occasion do earnestly desire to express our gratitude and thanks to the various Medical Services we have come in contact with, for their skill and perseverance shown for our good,
>
> *And Whereas* we do earnestly desire to express our humble appreciation to the Nursing Sisters who have so heroically befriended us in time of need,
>
> *And Whereas* we do earnestly desire to express our deepest and sincerest regard to the Red Cross, Y.M.C.A., and all other organisations who laboured so much for our Comrades of the Great War and us.
>
> *So Be It Resolved* at this First Dominion Gathering of Amputation Cases of the Great War, to again re-affirm our faith in Canada and the Empire as we were privileged to do in the hour of test that we may take our place in the line of Canada's forward march of to-morrow as citizens and useful men.

The resolution was carried unanimously, and the spirit which prompted its proposal is well displayed in its bold pathetic words.

WE deeply regret to announce the death of Sir Sydney Beauchamp in London, on Nov. 22nd, as the result of a street accident.

Sir Edward Marriott Cooke, K.B.E., M.B., who has recently retired from the Board of Control, has been appointed an unpaid Commissioner of the Board of Control for Lunacy and Mental Deficiency.

Colonel George Sampson Elliston, C.B., M.R.C.S., who died at Felixstowe on Nov. 20th, was for many years medical officer of health for the Borough and Port of Ipswich, and was well known in the Eastern counties as a pioneer of ambulance and volunteer training.

THE first meeting of the Dental Board of the United Kingdom will be held at 44, Hallam-street, London, W., on Wednesday, Dec. 7th, at 2 P.M., when the Right Hon. Francis Dyke Acland, M.P., will take the chair. The Board will continue to sit until the termination of its business.

AT the Royal Society of Medicine on Nov. 28th, at 5 P.M., an Occasional Lecture will be delivered by Dr. Guelpa, of Paris, on the Treatment of Diabetes and Gout by Disintoxication. The lecture will be open to Fellows and visitors. On Dec. 7th Sir Berkeley Moynihan will deliver, at 9 P.M., a short illustrated address on Medicine and Art.

Public Health Services.

WILLESDEN MUNICIPAL HEALTH SERVICE: A LOCAL DISCUSSION.

THE question of the municipal health service and its encroachment on private practice, in the area of the Willesden Urban District Council, has for some time past come under the notice of the Willesden branch of the British Medical Association. The scheme, which has received a large measure of public support and is rapidly extending, is criticised by the local medical practitioner on the following grounds:—

1. The health service is now largely devoted to remedial and curative measures at the local clinics, to the prejudice of the work of preventive medicine proper to a public health department.

2. By the establishment of this service, which until recently has been free to all mothers and children of school age without question as to their ability to pay for advice and treatment, the council's health authority has been competing on unjust terms with the local practitioner. The position has not been materially improved by the scale of charges (here reproduced) which came into force on Oct. 1st.

WILLESDEN U.D.C. HEALTH DEPARTMENT.

MEDICAL SERVICES—SCALE OF CHARGES.

Ordinary Benefits.

On payment at the Municipal Clinics of a registration fee of 2s. 6d. per person, the following ordinary benefits will be available for one year from the date on which the registration fee is paid:—

Out-patient medical and dental care, supervision and treatment of mothers and children under 5 years of age resident in Willesden, and children attending Willesden public elementary schools, including the benefit of the following:—
  - (*a*) Mothers' clinics; Baby clinics; Minor ailment clinics; Throat, nose and ear clinics; Eye clinics; Ringworm clinics; Dental clinics.
  - (*b*) Specialist consultations.
  - (*c*) Prescriptions.
  - (*d*) Home nursing.

Additional Benefits.

Additional benefits are available at the following scale of charges:—

Provision of artificial teeth	Cost price.
,, surgical instruments	Cost price.
,, spectacles	2*s.* 6*d.*
Repairs to spectacles	1*s.* 0*d.*
In-patient treatment at the Municipal Hospital as follows:—	
Confinement cases	£2 (inclusive fee).
Operative treatment of tonsils and adenoids	7*s.* 6*d.* ,,
Diseases of women	3*s.* 0*d.* per day.
Diseases of children up to school-leaving age	1*s.* 6*d.* ,,

General Conditions.

The council will consider the remission of the above charges (excepting repairs to spectacles, 1*s.* 0*d.*; and the registration fee, 2*s.* 6*d.*) in cases whose circumstances are below the council's scale. The council reserve to themselves the right to refuse treatment where accommodation or equipment is not available.

3. The local practitioner has not been consulted in the establishment of this service, nor asked to coöperate in the work, which is carried on by full-time medical officers, under the direction of the medical officer of health.

At a full meeting of the Willesden division of the B.M.A., held at St. Andrew's Parish Hall, Willesden High-road, on Nov. 15th, the recent activities of the council's health department were condemned both on the ground of abstract justice and of expediency from the public service point of view, and debate centred on the method of procedure to be adopted. It had originally been intended to receive a deputation of the local Ratepayers' Union, and to hand them copies of resolutions, but this plan was abandoned owing to representations from the Society of Medical Officers of Health. After full discussion, it was decided not to receive a deputation from a lay body at a medical meeting, but to send to the council, to the three local Ratepayers' Unions, and to the press copies of a memorandum drawn up by a special committee, and of a number of resolutions passed at the meeting itself. These documents may be summarised as follows:—

General Criticism of Council's Health Policy.

The principle underlying municipal health policy in Willesden appears to be to concentrate in the hands of the whole-time permanent officers of the and they content themselves with the conclusion that "the tuberculous infection pursues quite a different course in guinea-pigs which have received an intracardiac immunising injection of bile-cultivated bacilli than it does in the controls." Amongst other interesting points in this valuable paper is the fact that the bacilli were found in apparently healthy lymphatic glands, in the dog, three months after the last injection.

THE SCHOOL OF TROPICAL MEDICINE AND HYGIENE IN CALCUTTA.

WE are informed that a few days ago, by permission of the Government of Bengal, the first course of instruction in the Calcutta School of Tropical Medicine was begun, whilst the Carmichael Hospital is now on the point of being opened, if not actually open. The provisional prospectus of the Schools of Tropical Medicine and Hygiene and the syllabus of their respective diplomas were recently issued, together with a note on the present position with regard to these institutions, including a statement of the financial support already received and of that for which the Government of Bengal is urged to make itself responsible. A brief outline of the origin of the Calcutta school was traced in these columns nearly a year ago[1]; reference was then made to the unlimited opportunities for teaching and research provided by the position and surroundings of the schools. It is hoped to organise research largely on the lines of the Rockefeller Institute in New York; the work of the schools and hospital will be chiefly directed towards solving the special problems of Bengal and the neighbouring provinces, and will aim at making the province self-supporting in the supply of highly-trained doctors and sanitarians and in the provision of medicines suitable for the treatment of diseases prevalent in Bengal. Indeed, the research side of the institute has been open for a year under the governing body of medical men, who control the endowment fund, subscribed by the public, with an income of over a lakh of rupees a year; and good work has already been recorded on kala-azar and leprosy. The Pathological Museum is in size unique among tropical museums; at the Tropical School training will be given for post-graduate instructors who will meet a great need in the province, and here special attention will be paid to the uses of indigenous drugs; at the School of Hygiene there will be held the first organised higher courses of hygiene instruction in India; and the Carmichael Hospital, regarded merely as a charitable institution, will amply justify the entire expenditure connected with it—all these institutions have been built and equipped from funds raised by Sir Leonard Rogers, whose knowledge of Indian diseases is unrivalled in breadth. As component departments of the general scheme their organisation is inter-related in a manner calculated to be not only of the utmost value in itself, but also a model for other countries to imitate; what is asked of the Government of Bengal is the annual contribution of Rs.3,92,000, a sum small in comparison with the benefits which will accrue to the province. The large sums contributed by the Governments of India and Bengal, by great commercial houses, and leading private individuals, both European and Indian, form proof of widespread confidence in the business organisation of the undertaking; but the tone of the note suggests that whilst refusal of the Bengal Government to accept the final responsibility for the upkeep is described as "incredible," such refusal may occur. The province has, it is pointed out, "the opportunity of taking up and developing a unique property, which is the envy and admiration of the whole civilised world." It must be hoped that the province will not let that opportunity go by. Its Government will, in any case, have to provide post-graduate instruction for the doctors and training in hygiene for the sanitary officers, of the province. A new scheme for these purposes would cost much more than the amount needed to finance the existing scheme. Specially interesting is a reference, in the portion of the note dealing with the School of Hygiene, to a suggestion of the director of the school, concerning the training of special instructors in personal hygiene; these would later be attached to the education department, in which their duties would consist of holding courses of instruction in the rudiments of personal and domestic hygiene for the schoolmasters of Bengal. The latter would then convey their knowledge to the children who attend their schools, and in that way the principles of sanitary reform would gradually permeate the population. It has been found almost hopeless to instruct adults whose ideas are fixed, and in the manner described above the Calcutta school would before long become surrounded by an atmosphere of increasingly intelligent public opinion which could not but further the usefulness of its work.

HOWARD MARSH.

THIS memoir[1] of Prof. Howard Marsh is an unassuming account, written with a simple charm, of a man who was alike unassuming and charming. Marsh's memory will be kept green without the aid of memoirs among a large series of patients, pupils, and friends, but it is well that there should exist a written record wherein those who did not know the man may read of a life devoted to work and duty and lived in all single-heartedness. Marsh came of stock which has produced many men eminent in various walks of life, for he was descended from East Anglian farmers. He received his early education at the Grammar School of Eye at a date when the local grammar schools of this country had far greater chances than they now possess of turning out exceptional men. His mind was turned towards medicine by his association with Dr. Miller of Eye, one of the old school of country medical men, whom he used to accompany on his rounds, and after serving an apprenticeship with his uncle, John Marsh of Clerkenwell, he entered St. Bartholomew's Hospital in 1858. He was house surgeon to Mr. Skey and afterwards house surgeon to the then comparatively new Hospital for Sick Children in Great Ormond-street. This institution made a new and valuable departure in 1863, and one which played a great part in determining the direction of some of Marsh's best work. For an after-cure department was started in 1863, under which children with chronic joint diseases were visited at their own homes after leaving the hospital by those who were competent to see that the treatment was continued systematically. At this hospital and at its daughter hospital, the Alexandra Hospital for Children with Hip Disease, Marsh laid the foundations of that knowledge of diseases of the joints which was so marked a feature of his professional life. In 1873 he was elected assistant surgeon to St. Bartholomew's Hospital, but not until 18 years later—namely, in 1891—owing to the extraordinary delays in promotion at the institution at that particular time, was he appointed full surgeon with a right to beds. Until that time he was dependent for any beds under his charge to the courtesy of his colleagues. Marsh, however, was always a remarkably young man for his years, and not only did he discharge his duties as full surgeon for 12 years with zeal and success, but on resigning this post in 1903 in the same year he was appointed Regius Professor of Surgery at the University of Cambridge. This compliment to one whose only previous connexion with the University had been as an extern examiner was still further signalised when, in 1907, on the resignation of Dr. Alexander Hill, Marsh was elected Master of Downing College. As a professor, as head of a house, and as Vice-Chancellor, Marsh profited by that faculty with which he was eminently endowed—namely, the art of getting on with people; he possessed it without

[1] THE LANCET, 1920, ii., 1268.

[1] A Memoir of Howard Marsh, F.R.C.S., D.Sc., M.A. London: John Murray. 1921. Pp. 86. 5s.

Government, who were unlikely to contribute, the charitable, who were unable to contribute on account of other claims, the patient when he was ill, or the patient when he was well. He thought that it was preferable to obtain the payment before illness. Lord Cave's Commission would only give money to the hospitals if the hospitals could find new money, and this was an attempt to find that new money.

Dr. R. A. Bolam did not think that the promoters of the scheme had made the benefits very clear. It was not explained to the insured that he had the use of the hospital endowments. He thought it would be preferable that the medical profession should give their services free. He personally preferred to be an honorary officer of his hospital.

Dr. J. F. Gordon Dill said that the scheme was the only one that gave hope of relieving the debt of the hospitals. It would help to prevent hospital abuse. As one of the promoters of the scheme he would be glad to have constructive criticism.

Sir James Galloway said that the hospital with which he was associated had no debt, a state of affairs which was attributable to the excellent business capacity of their administrative staff. His main concern was whether the scheme, should it be successful, would be likely to interfere with their subscribers. He did not, however, think the scheme would be a permanent success, since, like all insurance schemes, it would need to be continuously boomed.

Mr. F. R. Smyth, L.D.S., said that there was no progressive diminution of the annual premium where benefits had not been paid for the preceding year, and so no inducement to continue the premium, such as was offered by insurance companies. He would like to know whether the scheme had been submitted to an actuary.

Mr. N. Bishop Harman said he was a supporter of the scheme. Times were different now from the days when the hospitals were founded. The State had no compunction about small payments from even their Poor-law patients. Why, therefore, should there be any compunction about accepting payments from the hospital patient?

Dr. A. Cox would rather see a straightforward insurance scheme, but he thought the present scheme worth a trial.

Dr. F. J. Poynton said that above all things the staffs of hospitals must preserve their honorary status. If the hospitals must have assistance it should come from the State.

Mr. Ernest Clarke thought the scheme was likely to appeal only to those who were sick.

Dr. Gordon J. Lane thought the scheme had not been properly considered, and found it difficult to believe that 2½*d.* a week could provide all the services offered, and yet leave a surplus for the hospital.

Dr. J. W. Kynaston pointed out that the scheme had been taken up at present by only three hospitals.

Sir Charles Ryall said that this was not the first insurance scheme adopted by hospitals. In the eighteenth century the Westminster Hospital set the fashion of admission by subscribers' letters which were distributed in proportion to the amount of the subscription. The real poor had thus been unable to gain admission, and it was the discovery of a poor woman in a dying condition, on whom all the hospitals of London shut their doors, since she had no subscriber's letter, that led John Marsden to found the Royal Free Hospital. Other hospitals had been forced to abandon the subscriber's letter.

In reply Mr. Eccles said he had obtained the opinion of several people associated with insurance undertakings that his scheme was financially a sound one. At St. Bartholomew's Hospital they now charged those of their in-patients, who could pay, £2 2*s.* a week, and he thought that the subscriber who found himself in hospital free, while his next-door neighbour was paying, would congratulate himself on his foresight in joining the scheme.

On being put to the vote the resolution was defeated by a large majority.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

Australasian Medical Congress.

THE next Congress will represent a departure from precedent and will be a meeting of the British Medical Association in Australasia, to some extent like the annual B.M.A. gathering in the United Kingdom. Mr. G. Adlington Syme has been elected President, and the meeting will probably be held in February 1923, at Melbourne. Presidents of sections and other office-bearers have not yet been nominated.

Charge of Manslaughter.

A death under anæsthesia occurred at the Adelaide General Hospital on July 21st, 1921. The patient was a young man who had sustained a severely cut hand. The resident surgeon on casualty duty administered ether with the assistance of a student and a nurse. The patient ceased breathing after having vomited. The medical superintendent was summoned and performed artificial respiration, and also cardiac massage through an incision. A second resident officer was directed to perform tracheotomy, which was done. Death was subsequently found to have been due to suffocation owing to the patient having vomited. At the coroner's inquest the medical superintendent stated that the anæsthetic was not administered in accordance with the hospital rule, which required his own presence. A prominent barrister, for the relatives, demanded a verdict of manslaughter against all the medical men, but the coroner gave a verdict simply of death under anæsthesia, though he made unfavourable comment on the hospital management. Next day an information was laid charging the three doctors with manslaughter and they appeared before the police-court. The case was postponed indefinitely owing to the procedure of prosecuting counsel, who, when the hearing was resumed on Sept. 5th, made no appearance, but wrote a letter to the magistrate intimating that he did not intend proceeding with the matter. The informations were thereupon dismissed.

War Memorial.

The Victorian Branch, B.M.A., has decided to erect a memorial in the hall of the branch to the members who lost their lives during the war. A commission has been given to Mr. C. Web-Gilbert, the leading sculptor in Australia, to execute a design submitted by himself in bronze at an estimated cost of £600.

Bubonic Plague.

Within the past three weeks a decidedly unpleasant situation has arisen in Queensland with respect to bubonic plague. It appears that a case occurred in Brisbane, which after death was recognised as plague. Nothing was allowed to transpire until some three weeks later when a second case occurred. Since that time a few further cases have been reported, together with one case from Townsville. Infected rats have been found from over a wide area of Brisbane, in Townsville, and as far north as Cairns. A steamer arrived at Sydney from Brisbane during the preliminary period before the declared case was announced; plague-infected rats have since been found in Sydney in the neighbourhood of the wharf at which this steamer discharged cargo. Dead rats have also been found in several coastal steamers. Vigorous measures have been taken for disinfection of steamers and cargo, and rat destruction has been actively undertaken. The Brisbane health authorities have been severely criticised for concealment of the first case and no explanation of their action has yet been offered. Up to the present the outbreak has not spread rapidly, but there is apparently a wide distribution of infection among the rat population in the coastal ports.

Motor Fatality.

On Sept. 23rd Dr. G. A. Paul, a well-known surgeon of the younger generation, lost his life in an accident near Sydney. Dr. Paul and Dr. Howard Bullock left Sydney in a motor-car in order to visit a country house;

corresponded with Nonne's reaction, but the other reactions did not show a similar parallelism. Dr. Tenzer's observations prove that a positive Wassermann reaction in the cerebro-spinal fluid is much commoner in congenital syphilis than in the acquired disease, and is indeed often the only change to be found. On the other hand, although the cerebrospinal fluid was affected in a comparatively high percentage of cases, the changes rapidly disappeared, and could not be regarded as indications of a permanent damage to the central nervous system.

LOCAL ANÆSTHESIA IN STOMATOLOGY.

THE reliance of continental surgeons upon local anæsthesia is in remarkable contrast with the practice of this country. Dr. Hewer Aboulker, laryngologist at the Mustapha Hospital in Algiers, has recently made the claim[1] that local anæsthesia is applicable in the severest operations for cancer of the tongue and pharynx, and that by its use he has been able to reduce materially the death-rate in his own practice. After experiencing an operative death-rate of 55 per cent. in 18 operations for bucco-pharyngeal cancer carried out under chloroform, he has not had a single operative death among 10 subsequent operations under local anæsthesia. It would be rare in this country to find so high an operative death-rate under chloroform, yet it is worth noting what may be accomplished without a general anæsthetic in cases where this may be contra-indicated. We are informed that in the whole city of Geneva there is but one apparatus for administering nitrous oxide, and that is kept at the university clinic purely for demonstration purposes. That nitrous-oxide anæsthesia is the method of choice in this country for dental extractions is indicated by the fact that in large towns, where skilled anæsthetists are available, so many operations appear to be carried out under its influence. Dr. B. H. Haines,[2] writing in a country where local anæsthesia is much used, seeks an explanation for the better results he has obtained under nitrous-oxide anæsthesia, and finds it in the freedom from the more or less violent reaction or exacerbation of systemic symptoms which commonly follows a local anæsthetic. He does not believe that the small amount of local anæsthetic used has enough toxicity to account for these symptoms, which he has noted as routine phenomena, but attributes them to the lowered local resistance dependent on temporary interference with the circulation of the blood. Whether this is or is not the correct explanation, the fact remains that patients who take gas well usually find that the painful fugue developing from a vague uneasiness through an ache to an agony ends more abruptly when the extraction has taken place under nitrous oxide than under local anæsthesia.

BLOOD-DONORS.

IN a recent number of the *Guy's Hospital Gazette* the editor protests against the too free use of students as blood-donors. He implies that they have been encouraged to act as donors, and it is greatly to their credit that they have so readily acceded to requests for blood. Later the editor of the *St. Bartholomew's Hospital Gazette* associated himself with this protest, pointing out that the medical student is a hard-worked person, little able to part with a pint and a half of blood. It may take three weeks for a normal individual to make good even the loss of a pint, and it is clear that students should not be expected, through sheer altruism, to work at a disadvantage for so long a time as this. We should regard it as perhaps justifiable to have at hand a few volunteers among the students, carefully chosen for their physical fitness, and to reserve them for cases of extreme urgency, but the principle should not be extended beyond this. The hospital journals raise a question as to the best procedure in institutions which may have to deal at any moment with cases of severe hæmorrhage. It is clear that, if students may not be used as donors, still less may the permanent staff of a hospital be expected to serve. None of them can be spared from their duties even for a day without detriment to the hospital.

In the United States of America, where blood transfusion is more frequently practised than in this country, there has arisen a class of "professional donors." It is unlikely that anyone can make a living out of this occupation alone, as the frequency with which the healthiest man can afford to lose blood is limited to three or four times a year. Nevertheless, these professionals have thought it necessary to their interests to form a "trade-union," so that their blood may command as high a price as possible. Matters have not yet reached this pass in London, though a beginning has been made by the insertion of advertisements for blood-donors in the newspapers, and unemployed workmen have been obtained for a modest sum from the Labour Exchanges. At the present time, however, few hospitals are able to offer adequate payment to blood-donors, and in any case a system of professionals living at a distance from the hospital would not solve the problem of how to proceed in a case of great urgency. At the present time a relative of the patient is used in some instances, or a volunteer is found among the younger patients admitted for minor surgical ailment. Probably it is in the more systematic use of this kind of donor that the best solution of the difficulty is to be found. If the house surgeon responsible for dealing with the emergencies were to make a point of always knowing of at least one suitable donor among the patients, their blood could be obtained with the minimum of delay. For the less urgent cases a relative or friend belonging to the right blood group could usually be found. Some hospitals no doubt already have a system of this sort in operation, but where it is found necessary to protest against the too frequent use of students as donors it seems probable that better organisation is needed.

POST-GRADUATE EDUCATION FOR LONDON.

A MEETING was held at the House of the Royal Society of Medicine on Friday, Nov. 18th, at which representatives of the British Medical Association discussed with the Fellowship of Medicine the future of post-graduate education in London. The conference was presided over by Sir George Makins, chairman of the Executive Committee of the Fellowship. It will be remembered that the Post-Graduate Medical Committee of the Ministry of Health, under the chairmanship of Lord Athlone, presented a report earlier in the year recommending that certain steps should be taken to organise post-graduate education in London. The recommendations included attachment of a post-graduate medical school to a centrally situated London hospital, the establishment of a central office to develop educational work, and the granting of substantial financial assistance from the Treasury. Since this report was issued the idea of a central hospital devoted to post-graduate work has been abandoned for the present, the large expenditure being inhibitory. But as all our readers know, the Fellowship of Medicine has been for a long time carrying out post-graduate work in London, and the purpose of the meeting was to see how far this work could be developed along the lines of the recommendations of the Athlone Committee, and to what extent and in what places the assistance of the British Medical Association might be expected in future developments. At the meeting, which was entirely informal, Mr. Herbert Paterson, speaking for the Fellowship of Medicine, pointed out that a scheme had already been organised for a six weeks' post-graduate course, to be held early next year, continuous and occupying the whole of each day. Whilst it was admitted that such a course would the books of the Ministry. The record cards dealing with casualties from all the theatres of war had been collected, and reached in number no less than 30 millions. Each week he received 794,000 letters. In a department of this size occasional mistakes must inevitably occur. In one town 100,000 cases might be successfully and efficiently dealt with and no complaint arise, but if one slip should occur in dealing with all that number, the Minister's life was made not worth living.

---

[2] National Anæsthesia Research Society, Bulletin No. 16, Nov. 15th, 1921, p. 4.

The functions of the Ministry were to restore the pensioner and to reinstate him in the social and industrial life of the country. They had 90 hospitals, controlled 14,000 beds in their own institutions and 10,000 beds in civil hospitals, and there were at present 158,000 pensioners under treatment for whom the Ministry defrayed the cost. By means of treatment and training in convalescent centres they were trying to restore these men as fit units to the field or factory. After previous wars disabled men were too often left as derelicts on the ocean of life. They served their country in its hour of need and returned to find their families pauperised, and 6*d*. a day their reward. He refused to accept the idea that the Ministry of Pensions should be run as a business institution. A business man could do what he liked with his own money. He could make bargains and cut losses, but that would not do with the trustees of public funds, who had to hold the balance between the interests of the taxpayer, and a just and generous treatment of those who had suffered in the service of the nation.

Pension Issue Office for Scotland.

An office in Edinburgh has now been opened for the issue of pensions to Scottish soldiers. The change of administration from London to Edinburgh will take place gradually, names being transferred in alphabetical order. Soldiers only are to be dealt with for the present, while naval and air force cases will be transferred early next year. The cases of widows and dependents are meantime to be administered from London.

VITAL STATISTICS OF LONDON

DURING OCTOBER, 1921.

IN the accompanying table will be found summarised statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious disease it appears that the number of persons reported to be suffering from one or other of the ten diseases notified in the table was equal to an annual rate of 19·3 per 1000 of the population, estimated at 4,531,971 persons in the middle of 1920: in the three preceding months the rates had been 10·3, 8·5, and 14·0 per 1000. Among the metropolitan boroughs the lowest rates from these diseases were recorded in Kensington, Chelsea, the City of London, Lambeth, Wandsworth, and Lewisham; and the highest in Islington, Finsbury, Shoreditch, Bermondsey, Battersea, and Greenwich. The prevalence of enteric fever was about 25 per cent. less than in the preceding month; of the 33 cases notified during the four weeks ended Oct. 29th, 6 belonged to St. Pancras, and 3 to each of the boroughs of Kensington, Chelsea, Hackney, and Camberwell. There were 28 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 27, 32, and 37 at the end of the three preceding months; the weekly admissions averaged 4, against 5, 5, and 7 in the three preceding months. The prevalence of scarlet fever again showed a marked increase—40 per cent.—over the preceding month, and was considerably higher than in any month of the present, or the three preceding years; in the month of October, 1918 (five weeks), the notified cases of scarlet fever number 1031, in 1919 (five weeks) 2179, in 1920 (four weeks) 3700, as against 4625 in the four weeks of

* Including membranous croup.

municipality the care (including treatment) of the child from before birth to school-leaving age, the services of these officers being placed at the disposal of all comers, and not only of the necessitous poor. This policy is opposed to the public interest, immediately because it involves unnecessary expenditure, ultimately because it must result in the formation of a class of practitioners wholly concerned in the treatment of disease in expectant mothers and in children, and the withdrawal of practice among such patients from the general practitioner.

Examination of the development of the system at the present time shows that the municipal service in Willesden is undertaking a work which, to a large extent, might be adequately provided for through other agencies. The service, thus overburdened, fails to carry out adequately its own peculiar functions. In other words, the present arrangements tend to neglect the preventive aspect of health work for the curative. This is extravagant because:

(1) Failure in prevention means an increase in avoidable sickness and disablement;

(2) The curative work can under present conditions be better undertaken by private practitioners;

(3) Persons able to pay for medical treatment are encouraged to obtain such treatment at the public expense through the public service;

(4) Owing to the excessive burden laid on the staff of the health service the work actually done cannot be adequately performed.

Here followed a series of notes illustrating the application of these general criticisms to the work of the several departments—viz., municipal hospitals, maternity and child welfare centres, and the treatment of school children.

Resolutions Passed at the Meeting.

1. That treatment at M. and C.W. centres should be confined to necessitous cases and in the case of school children to those cases where the parent fails to provide treatment recommended by the school medical officer or private practitioner.

2. That the Dunfermline scheme should be adopted in Willesden to ensure (*a*) that each child requiring treatment will in the first instance be sent to the family doctor, and (*b*) that the family doctor should have the right to refer cases to the clinics.

3. That part-time practitioners should be employed at the clinics as far as may be practicable.

4. That it is undesirable for wards in infectious diseases hospitals to be used for the treatment of non-infectious diseases and for maternity cases.

5. The division endorses the opinion of the Ministry of Health that the Willesden Hospital should not be used for non-infectious cases until the needs of infections cases are dealt with. Further, that the hospital should not be used for non-infectious cases at all, as there is no accommodation for mixed or doubtful cases even in normal times.

6. The division protests against the leaflet entitled Scale of Charges because this is practically a municipal service and as such directly opposed to the policy of the B.M.A.

7. The division calls the attention of the Willesden ratepayers to the health policy of their council, which threatens to destroy the freedom not only of the medical profession but of every individual in the community, and urges the ratepayers strenuously to oppose at the next municipal election those who are responsible for a policy which the medical profession of Willesden considers to be a serious and increasing menace to the public health.

NATIONAL PROVIDENT SCHEME.

A MEETING of the Marylebone division of the British Medical Association, held at 11, Chandos-street, W., on Nov. 16th, was given up to a discussion of the National Provident Scheme. Mr. W. McAdam Eccles moved a resolution:—

> That this meeting approves of the National Provident Scheme for hospital and additional medical services.

He said that the financial position of the voluntary hospitals in London was serious. In the past annual deficits to the amount of half a million had been largely made up by extraordinary grants from King Edward's Hospital Fund and the National Relief Fund, which would no longer be repeated. Some scheme for finding new money was therefore essential. The Cave Committee suggested three sources: (1) mass contributions from wage-earners; (2) a scheme resembling the Oxford scheme; (3) the Sussex scheme modified for London.

It was the third scheme which they were now considering. This scheme provides hospital treatment, consultations, nursing, specified dental treatment, X rays, electrical treatment, massage, laboratory investigations, and ambulance service. The advantage to the patient was that provision was made during health and that no payment was necessary for hospital maintenance during sickness. To the hospital it meant the maintenance of the voluntary system with an adequate income and no necessity of making appeals, which sometimes cost more than they produced. The general practitioner would benefit by having all the advantages of the scheme for his patient at his discretion. The staff of the hospitals were to receive 25 per cent. of the money received, and in addition, a fund was to be established from which fees for consultations at the patient's house were to be paid. The scheme, he said, would in no way increase the "hospital population," nor would it increase the sickness incidence: the voluntary hospitals were at the present moment actually dealing with the persons who should become members of the scheme.[1]

Dr. C. O. Hawthorne, in opposing the motion, criticised the financial basis of the scheme; he regarded this as unsound and as unlikely to be successful. The persons to whom the appeal was to be made were already taxed every week for one health service and would hardly welcome a further burden; in the nature of things most of the members would receive no benefits even over a series of years, and lapses would certainly be numerous; those admitted to hospital under the scheme would find there others who had paid no annual subscription and yet enjoyed the same benefits as the insured; and there was no certainty that a hospital bed would be available for a member when he required it. Thus, economically, the insurance was not a good one, for the benefits were not confined to policy-holders, and when the contingency contemplated by the policy arrived there was no guarantee that it would be met. Dr. Hawthorne also commented on the admission of persons without a previous medical examination; on the right, immediately after the payment of a single premium, to claim the full benefits of the contract; and on the absence of an income limit in the case of persons included within the scope of the National Insurance Act. He questioned the ethical defence of a procedure which would take the capital values of the hospital buildings, equipment, and endowments and would utilise these, not for purposes of philanthropy, but as the basis of a scheme of industrial insurance. Were the scheme successful financially the partial acquisition of the hospitals as at first proposed would gradually lead to the complete conversion of these institutions into nursing homes resting on a commercial basis and run for the benefit of the subscribers to the scheme; and the sick poor, for whom the hospitals were originally intended, would be relegated to the Poor-law infirmaries. A further consequence would be the conversion of the members of the honorary medical staffs into paid officers of an insurance organisation. Further, was it likely that voluntary subscriptions and donations would be given to organisations which had lost their charitable character and had become part and parcel of a commercial proposition? The voluntary hospital system rested on three supports—voluntary contributions, voluntary administration, and honorary medical service. Every one of these supports was undermined by the scheme now proposed, and both public and professional interests called for its rejection.

Discussion and Reply.

Mr. H. S. Souttar, supporting the motion, said that Dr. Hawthorne's argument was founded on two parts, first that the hospitals could continue to carry on, and second that the "sick-poor still existed." Neither of these is quite true. The hospitals had to get money, and the only possible sources were the great deal depends upon individual intelligence, and it is no uncommon thing to see a smart boy making every use of small residual hearing side by side with a dull one who has four times as much but does not, apparently, know what to do with it.

---

[1] See also article by Mr. Eccles in THE LANCET, 1921, i., 1057.

There appear, from time to time, persons who have evolved schemes, more or less original (chiefly less), for "re-educating hearing." Such schemes are neither heaven-born nor new, they are at least as old as the first century of the Christian era, when Archigenes advocated intensified sound and trumpets to remedy defective hearing. Many of these ideas are well exploited, highly vaunted, and then sink into oblivion. A few, a very few, survive, often much modified. What is so deplorable about them is that each one leaves behind it a long trail of wounded—disappointed deaf adults, deaf children, whose education has been neglected for the prosecution of vain experiment, and parents who have bought experience. In practically every case the promoter of the scheme is completely ignorant of the psychology of the deaf child, the method (proved by long and practical experience) of his teaching, and the fact that every teacher of the deaf worthy of the name is making the utmost use of residual hearing every minute he is at work *and by better methods*. The thing is unfortunate, but the poor inventor is by no means alone in his ignorance; he merely shares in that remarkable ignorance of the deaf child displayed by many of the medical profession (even including some specialists), an ignorance which appears frequently to lead doctors into making the astounding and wholly unwarranted statement that a child will regain its hearing at the age of seven! I would, further, emphasise the fact that the deaf child stands upon an entirely different plane to the deaf adult. The latter is already in possession of language and automatic speech. Attempts at restoring hearing in his case, by suggestion or other means, may be successful, but to apply the same reasoning, the same arguments, the same treatment to the deaf child is unscientific and useless. It is to construct the same hypothesis upon totally different and totally unsuitable foundations.

In conclusion, I would point out that there exist individuals who, having found a hypothesis, become so enamoured of it that they work upon it in what Dr. Millais Culpin has so aptly called "logic-tight compartments." Therein enclosed, impervious to every fact which may vitiate their calculations, they justify themselves by a pseudo-reasoning satisfactory to their own peculiar mental complex. Some of the so-called re-education schemes would appear to have been framed in this way.

I am, Sir, yours faithfully,
MACLEOD YEARSLEY.
Welbeck-street, W., Nov. 15th, 1921.

PHYSICAL EXERCISE IN HEART DISEASE.

To the Editor of THE LANCET.

SIR,—An annotation in your issue of Nov. 5th drew the attention of your readers to the value of graduated exercises in the treatment of heart disease. Although the method is an old one, its proper value has as yet found but little appreciation. This is particularly the case in the provinces, where it is practically unknown.

But if this treatment is to be successful it is necessary to take the following precautions:—

1. The exercise prescribed in each case should bear a certain relationship to the condition of the heart muscle.
2. The method ought not to be used in cases which show grave myocardial lesions.
3. In advanced cases it is advisable to make the reaction to work of the arterial pressure and pulse-rate as a sort of standard by which the amount of exercise to be taken can be gauged. Suppose a given amount of exertion produces an increase of pressure, say 10 mm. Hg, and this reaction is considered a moderate one, then the exercises are so graduated that the subsequent treatment will produce about the same reaction. Repeated exercises of increasing intensity, if this method is applied, will not produce a greater strain.
4. In advanced cases one group of muscles should be exercised at one time, the rest remaining passive. If all muscles are exercised at one and the same time an undue strain is brought to bear on the heart, unless the exercises are of so mild a nature as to be ineffective for the purpose. I found the Zander system, which I have been using for the last eight or nine years, the best method for carrying out this treatment.
5. In order to avoid all possible strain it is best to start with more difficult exercises, gradually going down to the easy ones, and then allowing a few minutes for rest.
6. It is advantageous to combine massage with exercises.
7. After the patient has carried out a course of treatment he should be recommended to take graduated walking and climbing exercise.

Graduated exercises carried out with due precaution give far better results in heart trouble than does any other form of treatment.

I am, Sir, yours faithfully,
Liverpool, Nov. 14th, 1921. I. HARRIS.

RICKETS AND VITAMIN DEFICIENCY.

To the Editor of THE LANCET.

SIR,—Dr. Amy Hodgson's admirable chemical and clinical study in your issue of Nov. 5th throws a valuable new light on the vexed problem of rickets. Any practitioner with experience of rickets could also cite cases in which the diet was in no sense deficient in vitamins. The discrepancies found by various experimental and clinical workers are explainable if we suppose that infants may have a varying capacity to absorb, or utilise, the vitamins presented to them; just as gouty and diabetic subjects have an incapacity to absorb other and grosser articles of diet. Too large a proportion of carbohydrates, or other indiscretions, might well diminish still further the capacity of absorption.

There are likewise thin, tuberculous disposed subjects who may take much fat, yet still remain thin and tuberculous disposed—unable perhaps to utilise the fat or the resistance-aiding vitamins which it contains. Some of these patients were rickety when young, as their deformed chests testify.

I am, Sir, yours faithfully,
E. WARD, M.D., F.R.C.S.,
Tuberculosis Officer, South Devon.
Paignton, Nov. 17th, 1921.

CLAYDEN *v.* WOOD-HILL.

To the Editor of THE LANCET.

SIR,—The report in your issue of Nov. 19th (p. 1073) upon this important medico-legal case fails, in my opinion, to bring out the facts quite clearly. Stated briefly, these were as follows: The patient sustained a fracture of the femur just below the small trochanter and was treated at Beccles Hospital by methods which were in accordance with the usual surgical teaching. She was not X rayed, because the apparatus at Beccles was not good enough to enable an X ray of the upper part of the thigh and hip to be obtained. She left the hospital at the end of eight weeks walking on crutches, and according to Dr. Wood-Hill's evidence and that of his partner, the fracture was then in a satisfactory position and the limb half an inch short. About ten days after her return home, the leg gave way under the body weight, and considerable pain and swelling occurred. I saw the patient 14 days after the incident, and operated upon the fracture four days later, finding the fracture united with angulation, the shortening being one and half inches.

The allegation of negligence was based upon: 1. A wrong diagnosis of the level at which the fracture took place, due to (*a*) the absence of an X ray, and (*b*) failure to examine and "set" the fracture under an anæsthetic. Unfortunately, Dr. Wood-Hill had been induced to commit himself to a sketch showing the probable level of the fracture, in which he placed it too low down in the femur. 2. A failure to treat the limb in an abducted position as the result of the wrong diagnosis. As a result of this plaintiff alleged that the fracture was malunited at the time that she left Beccles.

Dr. Bullock was driving, and in attempting a sharp curve in the road the car overturned and both were pinned beneath it. Dr. Paul died shortly after being released and Dr. Bullock was severely injured.

September, 1921.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Indian Voluntary Hospitals.

INDIAN hospitals are not, as a rule, supported by voluntary contributions, but some hospitals, for example those of the Dufferin Fund and the Walker Hospital, Simla, are supported in this way. The difficulty experienced by hospitals at home is being fully shared by the Indian institutions, and great efforts are being made to collect funds. Ladies in prominent official positions are taking an active part in helping to raise money, and entertainments are being held in Simla and elsewhere for this purpose. At a recent meeting of the Countess of Dufferin's Fund, Lady Reading made a strong appeal for the support of the fund, which controls a very large number of hospitals for women throughout the Indian Empire. Commenting on the need for support of the League for Maternity and Infant Welfare, Lady Reading emphasised the importance of the provision of trained nurses and midwives. She pointed out that except in the presidency towns such training involved hospitals under medical women. If the training was to be good and the work successful experienced medical women and equipment for these hospitals were essential. The formation of the Women's Medical Service in India gave great impetus to women's hospitals by relieving the committees of the difficult task of finding and paying the salaries of medical women. The funds so set free were used to provide the hospitals with other requisites. The number of labour cases has increased, and nearly all the hospitals under the Dufferin Fund were now in a position to give a good practical training to nurses and midwives; but nearly all of them were also in a position of financial difficulty.

Indian Science Congress.

The ninth annual meeting of the Indian Science Congress will be held in Madras from Jan. 16th to the 21st, 1922. The Medical Research Section of the Congress will then meet for the fourth time. The honorary local secretaries are Captain Clive Newcomb, I.M.S., chemical examiner, Madras, and Dr. Mohammad Azizullah Sahib Bahadur. It is hoped that a large number of delegates from the other provinces of India will attend the Congress.

Health Officers in India.

At a conference of health officers held recently at Calcutta, it was decided to form a public health association for Bengal, and to send a deputation to the Health Minister to represent the grievances of the officers. It was also decided to urge that the service should be provincialised, or, in the event of the officers being controlled by the local board, that their appointments or dismissals should be in the hands of a board of sanitary experts who would also possess power to transfer officers. The health officers also asked for first-class travelling allowances and immediate increase of salaries.

Famine Code Committee.

Owing to the almost complete failure of the crops considerable areas in the ceded districts of the Madras Presidency have been declared to be in a state of famine, and a number of Government relief works have been instituted in order to carry the hard-hit ryots over the period until the next crop may be expected. Government relief works are controlled under rules laid down in the Famine Code, but a discussion recently held in the Legislative Council made it evident that a certain amount of dissatisfaction existed regarding the rigid manner in which the rules were said to be adhered to. In order to investigate the matter the Government appointed a committee under the chairmanship of the Famine Commissioner. The committee is composed mainly of non-officials from districts commonly affected with scarcity, but also includes two executive engineers who have had experience of famine work, and the Sanitary Commissioner. Medical opinion is required as to the physical capacity of the people for work, the question of emaciation due to insufficiency of food, the sufficiency of the various diet scales laid down in the code, and the general questions of sanitation of camps, &c. In connexion with diet scales the work of Colonel McCay, I.M.S., of Calcutta, is of interest, as his findings are somewhat antagonistic to the opinions commonly held by the layman in this country.

Ayurvedic Committee.

Mention was made some time ago in these notes of a report on Ayurvedic drugs by Dr. Koman, who carried out a prolonged investigation into the therapeutic value of the most important of these indigenous medicines. The Government have now gone a stage further, and have recently decided to appoint a small committee consisting mainly of non-officials to report on the question of the recognition and encouragement of the indigenous systems of medicine in vogue in this Presidency. The object of the proposed inquiry is to afford the exponents of the Ayurvedic and Unani systems an opportunity to state their case fully in writing for scientific criticism, and to justify State encouragement of these systems. In order that a preliminary programme of work should be drawn up, and that some indication might be given of the lines on which the inquiry should proceed, the Government nominated Khan Bahadur Muhammad Usman Sahib Bahadur as chairman, and Dr. G. Srinivasamurti as the secretary of the proposed committee. Of the ten members three general practitioners from Madras City are included, Dr. U. Rama Rao, Dr. A. Lakshmipathi Garu, and Dr. M. Subramania Ayyar; whilst the Ayurvedic practitioners are represented by K. G. Natesa Sastri Avergul, of the Venkatarama Dispensary, Madras, and C. T. Arumugam Pillai, of the Ayurvedic Dispensary, Georgetown, Madras.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

A Scientific Expedition to Peru.

EDINBURGH University has a special interest in the expedition organised by the Royal Society which leaves England this week-end for Peru, owing to the fact that Dr. J. C. Meakins, professor of therapeutics, is acting as deputy director to the expedition. The main object of the expedition is the study of the circulatory and respiratory systems amongst those who live at the high altitudes of the Andes. There is a large mining population in the villages some 16,000 ft. above sea-level, and it is reputed that these people are able to perform much heavier work than can be done by any other persons in so rare an atmosphere. Modern methods will be used in the investigation, and the results may prove of real value.

Work of the Ministry of Pensions.

The Rt. Hon. J. Ian Macpherson, M.P., at a meeting which he addressed at Oban recently, stated that shortly before he went to the Ministry of Pensions no less than 331 million pounds were required by the State for the provision of pensions—a sum six times the amount of the whole national expenditure at the time he entered political life. The Ministry of Pensions was engaged at that time, he said, in the biggest work that any public department in the world had ever undertaken. Of all those who had served in the Forces, one in three had been the subject of a pension, or, stated in another way, 3½ million persons were on

GENERAL COUNCIL OF MEDICAL EDUCATION AND REGISTRATION.

The opening of the winter session of the General Medical Council took place on Nov. 22nd, under the presidency of Sir Donald MacAlister.

The President commenced his address from the chair by pointing out that under the new Dentists Act the Privy Council is empowered to appoint three qualified dentists to be additional members of the General Medical Council, who must also be members of the new Dental Board, constituted under the Act. He stated that the following had been appointed: Mr. W. H. Dolamore, Mr. W. H. Gilmour, and Mr. W. Guy.

Dental Board of the United Kingdom.

The President continued :—

"With special satisfaction I announce that the Privy Council have appointed, as the first Chairman, the Right Hon. Francis Dyke Acland, M.P., already well known to the Council for his distinguished public services, and in particular for his fruitful labours as Chairman of the Departmental Committee on Dental Practice. It is vouchsafed to few such Committees to see their recommendations so promptly and effectively embodied in actual legislation. The Council has loyally coöperated with the Government and with the dental profession in shaping the amended law; and it cannot but rejoice that Mr. Acland has been induced to accept the responsibility of guiding the professional body, which this law has established, through its first stages of organisation and operation. For over 40 years the Council has had the duty of regulating dental education and registration under the imperfect Act of 1878. The Dentists Register for 1922, now nearly complete, will be the last to appear under its authority. The much larger volume bearing that name will henceforth be the work of the Dental Board. The long experience of the Council and its officers will be placed unreservedly at the service of the members of the Board when they take up their laborious and delicate task under Mr. Acland's direction. The new Act leaves to the Council certain important duties relating to dental education, examination, and discipline. These necessarily imply much mutual consultation and coöperation between the Council and the Dental Board. For this reason alone it would appear to be highly desirable that the office-buildings of the Council and of the Board should be adjacent and permit of ready inter-communication. The site to the north of this building is at the disposal of the Board, should it take the view I have mentioned concerning the convenience and economy of erecting its offices there.

The law gives power to the Council to act in dental matters by an Executive Committee, including at least one of the additional members. It will be expedient to set up this Committee at once. Probably you will think it proper to follow the analogy of the Act; and, as the Council for dental purposes consists of ordinary and additional members, to constitute the Dental Executive of the ordinary members of the Executive with an additional dental member. Various orders, rules, regulations, &c., must without delay be framed by the Board, and these have in general to be approved by the Council before they become operative. In order to avoid the expense and inconvenience of frequent short meetings of the Council for the purpose of considering and expressing such approval, it would be advisable that this power should, at least in the first instance, be delegated to the Dental Executive Committee. It is regarded as certain that one or more meetings for the purpose will have to take place during December, in order that the Board may get to work at the beginning of the new year. It will also be necessary that the Council's own Standing Orders should be thoroughly revised, if only for the purpose of eliminating the parts made obsolete by the Dentists Act, 1921, and of adapting the remainder to altered conditions. I shall propose that the revision be remitted to the Executive Committee for report to the Council in May."

The Registration Figures for 1921.

During the current year (1921) up to the present date, it appeared from the President's address, the number of practitioners registered in the Medical Register was about 1600, as compared with 1457 for the whole year 1920. The number of medical students registered in 1920 was 2531; at the present date the registrations for 1921 approached, he said, 1500, a much more manageable number than before. The number of registered dental students shows a proportionate reduction from 560 to 320, which is about average number before the war.

Reciprocity in Practice.

The President re-stated the position of medical reciprocity between this country and Belgium, and gave the interesting information that, as between this country and Spain, the whole question is being reconsidered, it being possible that fresh legislation on the part of Spain will admit of reciprocal recognition of professional qualifications. Applications, he added, had been received from certain new universities in South Africa, now legally constituted within the Union, and the Executive Committee of the Council, after consideration of the particular courses of professional study, had agreed to recognise the degrees as qualifications registrable in the appropriate list of the Medical Register.

Practice of Midwifery in India.

On the subject of the standard of obstetrical knowledge attained to by those holding degrees and diplomas from Indian universities, important communications, said the President, had been received from the universities, from the Indian Government, and from the Secretary of State for India. He continued :—

"In some cases it is reported in the memorandum on the whole subject prepared for the Executive Committee that amendments in the University Regulations concerning instruction in midwifery have been or will be made. In others that any improvement of the existing conditions will require time and involve expense. The Government of India explains, through the Secretary of State, that the question of extending the facilities for midwifery training in Indian university medical schools has for some time been under examination; but urges that, in view of certain present conditions, further time should be granted for improvement before the Executive Committee decides on the question of withdrawing its recognition from Indian qualifications.

"The Secretary of State, 'while deeply impressed by the considerations urged by the Government of India, fully appreciates the importance which the General Medical Council rightly attach to the fulfilment, by individual candidates for a licence to practise, of the midwifery practice enjoined in the [Council's] resolutions.' He deems it eminently desirable that the Indian medical schools shall equip themselves with the clinical and other facilities necessary to enable Indian graduates desirous of registration in England to comply with the Council's requirements; but he asks the Council to allow to the several universities a suitable extension of time within which to reform their midwifery and gynæcological curricula, if willing and able to do so. He further offers to request the Government of India immediately to depute an experienced medical officer, fully conversant with the practice of gynæcology and obstetrics, to visit in turn the Indian medical schools, and to explain the nature of the requirements which are considered essential if their respective degrees are to continue to be recognised in this country. This officer would transmit for communication to the Council a report on each University medical school, setting forth under proper heads such information as would assist the Council in coming to a decision regarding the recognition of its degrees. The Indian Legislative Assembly has, moreover, passed a resolution recommending to the Governor-General of India in Council that the various Local Governments be advised to make more satisfactory arrangements for giving practical training in midwifery to students undergoing instruction for medical degrees and diplomas, and to bring the training up to the standard of the universities of the United Kingdom where it is not already so. The Legislative Assembly also asks that further time may be given by the Council before a final decision regarding recognition is taken.

"In view of the replies of the majority of the universities, which indicate their purpose to improve the standard of their requirements in midwifery, and of the representations of the Indian Government and the Secretary of State, the Executive Committee have resolved to postpone the consideration of the question of recognition from February, 1922, to a later date, and in the meantime to accept the suggestion made by the Secretary of State that a report, on the matters detailed in his official letter, should be obtained and communicated to the Council. The Committee have intimated to the Secretary of State that it is prepared to nominate to the Government of India a member of the Council, who should accompany the medical officer appointed to visit the Indian universities, and be associated with him in framing the report in question."

The Inspection of Examinations.

The President stated that a cycle of inspection and visitation by which the Council ascertains the standard last month. This disease was proportionally most prevalent in St. Pancras, Islington, Finsbury, Shoreditch, Bethnal Green, Poplar, Battersea, and Greenwich. The Metropolitan Asylums Hospitals contained 6154 scarlet fever patients at the end of the month, against 3722, 3408, and 4817 at the end of the three preceding months; the weekly admissions averaged 1000, against 567, 407, and 810 in the three preceding months. Diphtheria also was considerably more prevalent—40 per cent.—than in September, and was higher than in any month of this year, or the three preceding years; 1803 cases were notified during the month (four weeks), against 937 in October, 1918 (five weeks), 1169 in October, 1919 (five weeks), and 1449 in October, 1920 (four weeks). The greatest proportional prevalence of this disease occurred in Hampstead, Finsbury, Shoreditch, Stepney, Bermondsey, Battersea, and Greenwich. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1969, 1709, and 2031 at the end of the three preceding months, further rose to 2777 at the end of October; the weekly admissions averaged 445, against 250, 209, and 322 in the three preceding months. Erysipelas was proportionally most prevalent in Holborn, Finsbury, Bethnal Green, and Bermondsey. Of the 5 cases of poliomyelitis, &c., 2 belonged to Deptford, 2 to Lewisham, and 1 to Greenwich; in the three preceding months the notified cases numbered 9, 13, and 10 respectively. Three cases of encephalitis lethargica were notified during the month, against 9, 5, and 5 in the three preceding months. The notified cases of cerebro-spinal fever numbered 3, against 7, 9, and 5 in the three preceding months. The 27 cases of puerperal fever included 3 in Fulham, 3 in Islington, and 2 each in Paddington, Poplar, Battersea, Wandsworth, and Lewisham.

The mortality statistics in the table relate to the deaths of civilians actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the four weeks ended Oct. 29th, the deaths of 3913 London residents were registered, equal to an annual rate of 11·3 per 1000; in the three preceding months the rates had been 9·8, 10·6, and 10·9 per 1000. The death-rates ranged from 8·9 in Wandsworth, 9·1 in Fulham, 9·6 in Stoke Newington, in Camberwell, and in Lewisham, and 9·8 in Woolwich, to 13·0 in Bethnal Green, 13·4 in Shoreditch and in Stepney, 13·5 in Holborn, 14·1 in Chelsea, and 14·8 in Finsbury. The 3913 deaths from all causes included 448 which were referred to the principal infectious diseases; of these, 11 deaths resulted from enteric fever, 10 from measles, 20 from scarlet fever, 33 from whooping-cough, 99 from diphtheria, and 275 from diarrhœa and enteritis among children under 2 years of age. No death from any of these diseases was recorded in the City of London. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in Chelsea, St. Marylebone, Holborn, Deptford, Lewisham, and Woolwich; and the highest in Finsbury, Shoreditch, Bethnal Green, Stepney, Poplar, and Bermondsey. The 11 fatal cases of enteric fever exceeded the average in the corresponding period of the five preceding years by 4; of these deaths 3 belonged to Lewisham and 2 to Bermondsey. The 10 deaths from measles were but half the average; of these 3 belonged to St. Pancras and 3 to Poplar. The 20 fatal cases of scarlet fever were 8 in excess of the average; of these, 3 belonged to each of the boroughs of Islington, Hackney, and Stepney, and 2 each to Hammersmith, Bermondsey, and Camberwell. The 33 deaths from whooping-cough were 17 above the average; of these, 5 belonged to Wandsworth and 3 to Camberwell. The 99 fatal cases of diphtheria exceeded the average by 40; this disease was proportionally most fatal in Hampstead, Stoke Newington, Finsbury, Shoreditch, Stepney, and Greenwich. The 275 deaths from infantile diarrhœa exceeded the average by 61; the greatest proportional mortality from this disease occurred in Hammersmith, Islington, Shoreditch, Bethnal Green, Southwark, and Bermondsey. The aggregate mortality in London during October from these principal infectious diseases was 38 per cent. above the average.

The deaths from influenza registered in London during the four weeks ended Oct. 29th numbered 40, against 15, 9, and 21 in the three preceding months, and 22, 18, 1721, 65, and 21 in the corresponding periods of the five preceding years.

TREATMENT OF VENEREAL DISEASES IN LONDON.—The Minister of Health and the County Councils concerned have consented to an arrangement under which the London County Council will be able, within defined limits, to make necessary modifications in its scheme for the diagnosis and treatment of venereal diseases, without the delay, previously unavoidable, in obtaining the consent of all the participating authorities to any such modification.

Correspondence.

"Audi alteram partem."

THE EDUCATION OF DEAF CHILDREN.

To the Editor of THE LANCET.

SIR,—Mr. A. J. Story's letter in your issue of Nov. 12th opens up a question that has long wanted ventilating, and never more so than at the present time. Perhaps I, who have a knowledge of deaf children and the methods of their education based upon some 14 years of unceasing work among them, may be permitted to speak plainly upon it.

I would first express my appreciation of those who cheerfully devote themselves to the instruction of deaf children, a work the most arduous and exacting in the teaching profession and which is followed with a steadfastness of which the reward lies only in results. Mr. Story points out that teachers of the deaf "would welcome with open arms anything that would give their pupils even a serviceable modicum of hearing ability." This I can cordially endorse, for I have found them ever ready to coöperate with the doctor and to help him to the utmost from their stores of experience, provided he will let them do so. Sufferers from deafness are ever upon the look-out for some heaven-sent miracle which will restore to them the sense they lack. They are consequently always eager to kneel in flocks, sublimely credulous, at the feet of anyone who professes to have discovered a short and easy road to the renewal of hearing. The little gods to whom they kneel have, most of them, clay feet. The persons who assert this ability to restore the "snows of yester year" do so from one of two motives—deliberate fraud or complete ignorance. Of the fraudulent I do not intend to speak; I have dealt with such impostors at other times and in other places, including the Court of King's Bench. They will continue to batten upon human infirmity and credulity so long as the press, intent upon giving the public "What it *wants*" rather than what it needs, will publish their advertisements.

But those who profess to restore hearing from a complete ignorance of the true conditions with which they have to deal stand upon an entirely different footing. I can say, with my friends Mr. Story and Dr. Kerr Love, that I have never known a single deaf child in schools to recover hearing power. But every day I see children, originally believed to be totally deaf, develop a certain amount of hearing as education progresses, which is quite another matter. This developed hearing is neither a new nor a restored hearing. *It was there all the time*, unrecognised, unused. The children had no conception of the meaning of the sounds they heard, no means of asking what they meant. Their hearing, too small to be of use in their physiological education, remained, so to speak, *latent*, until the gradual acquisition of language by education under the oral system brought appreciation of it to its possessor. These are the children which, getting into the hands of someone ignorant of the real facts, will respond to education. Such children make no response to tests when first examined, and to decide whether they have or have not any residual hearing is often a matter of great difficulty. Once education is begun and the child is watched and tested repeatedly, some slight hearing—it may be anything from mere perception of sound to complete vowel hearing as described by Mr. Story—will gradually unfold as teaching progresses and the mind is awakened to appreciation. Every teacher of the deaf knows this; it is his business and he makes every possible use of it. Furthermore, some of the effect of education may be delayed, and I have noticed repeatedly how boys and girls with a limited amount of residual hearing, will, as it were, "blossom out" within a few months of their transference (at 12½ or 13 years old) from the elementary to the secondary school. Of course, a without such prescription or order of a medical practitioner, the registered pharmacist shall only sell such poison with a printed label which shall have printed upon it the maximum pharmacopœia dose and the description of the antidote, if any, to such poison, together with the name and address of the seller of such poison; (c) as regards such poisonous articles as are sold for domestic or commercial purposes, not being for human consumption, such poisonous articles shall be supplied only in distinctive bottles or containers with the words "poisonous, not to be taken" legibly inscribed upon a label thereon, together with the name and address of the seller.

Clause 9 makes it unlawful for a manufacturing or wholesale chemist to supply any poison or poisonous matter, except to a person who has been duly registered and whose name is on the Pharmaceutical Register: Provided that it shall be lawful for the council of any borough or urban district to grant a license to a person requiring poisonous substances for the use or production of commercial articles only where the obtaining of such poisons does not need the authority of a qualified medical practitioner. No person shall carry on business as a wholesale or manufacturing chemist who is not or does not employ at least one person who is on the Pharmaceutical Register. Clause 10 gives power to local authorities as defined by the Act under certain circumstances to grant licenses to persons to sell non-poisonous articles mentioned in the British Pharmacopœia for a period not exceeding one year at a time. Clause 11 places the Pharmaceutical Register under the control of the Central Council. Clause 12 states that no advertisement in connexion with the sale of any medicinal article shall refer to the curative powers of such medicinal article with reference to more than three specific diseases or complaints, which three diseases or complaints must be of a similar pathological character, and no such advertisement shall be issued without the previous sanction of the said Central Council. Clause 13 is the penalty clause, and provides that any person infringing the provisions of the Act with regard to the sale of poisons shall be liable on summary conviction to a fine not exceeding £5 for every offence. The Act is not intended to apply to Ireland.

The Prorogation.

Parliament was declared by the Lord Chancellor prorogued till Monday, Jan. 30th, 1922. The Royal Assent was given to a number of Acts, including the National Health Insurance (Prolongation of Insurance) Act.

HOUSE OF LORDS.

THURSDAY, NOV. 10TH.

Hindrances to Scientific Research.

The Marquess of **CREWE** called attention to the hardship caused to teachers and students of science in universities and colleges by the application of the provisions of the Safeguarding of Industries Act to the apparatus and material necessary for education and research in chemistry and physics. He said that the Safeguarding of Industries Act and the German Reparations Act had exercised a distinctly hampering effect upon both research and the teaching of many branches of science. A distinguished professor of chemistry at one of the older universities wrote that there was no doubt that these Acts had had the effect of appreciably diminishing the amount of research work that could be done in the laboratory. The delay, he said, was never less than three months in the delivery of chemicals required for research. Time had to be given up to the preparation of materials for which it was not possible to wait so long. There was also delay in getting German books. Owing to the increased cost of materials some of the poorer students were known to spend on the purchase of chemicals money they ought to have spent on food.

Viscount **HALDANE** supported Lord Crewe in the course he had taken, and urged the Government to take steps adapted to get rid of the difficulties or to mitigate them. Professors were suffering great hardships at the present time. The other day he was told by a very competent person who had been working in the laboratories at Cambridge, which were supposed to be the best they had in this country, and in the physical laboratory in a German university, and the equipment of the German laboratory, although it had not the positive advantages of the laboratory at Cambridge, was enormously superior because it had a much better equipment.

Viscount **PEEL** (Minister of Transport), replying for the Government, said if the requirements of scientific and educational institutions imported from abroad were to be exempted from duty the assistance given by the Act to manufacturing industries would be diminished, and besides it would be difficult, if not impossible, to say which institutions should be given the exemption and which should not. As regarded the question of cost, the cost of the production of these things was quite small to the running and working of these laboratories. It had always been a complaint that there were very few opportunities for scientific workers in this country. Supposing this Act was a success and in four or five years' time these industries could stand by themselves, a very much wider field would be provided for scientific workers, and if scientific men would help manufacturers the development would be very much expedited. If the Act were repealed we should get back to the position we were in before the war and be dependent upon Germany and other countries for the supply of these goods He promised to see that the whole subject was placed adequately before the Minister of Education.

HOUSE OF COMMONS.

WEDNESDAY, NOV. 9TH.

Voluntary Hospitals Commission.

Mr. **LEONARD LYLE** asked the Minister of Health whether, under the terms of his departmental paper 1402, giving the terms of appointment of the Voluntary Hospitals Commission, the announcement that after the first emergency grant further grants would be only made against fresh money raised by the hospitals meant that they could not reckon, for the purposes of obtaining assistance, any ordinary revenue which they might receive in the current years; and whether, since this condition would prejudicially affect the poorer hospitals, which had practically tapped all sources of income and which now saw, at all events for the present, no further new sources of revenue in sight, he would in the interests of these poorer hospitals investigate the operation of this condition.—Sir A. **MOND** replied: The amount by which the income of a hospital for 1921 exceeds the income for 1920 will be reckoned as new money for the purpose of calculating the grants. In cases where the hospitals of a given area agree to combine for this purpose their aggregate income can be made the basis for calculating new money. As regards the second part of the question, I understand the King Edward's Fund are proposing to confer with the London hospitals as to the best method of raising their share of the anticipated deficit on the year's working.

Board of Control and Mental Defectives.

Mr. **LESLIE SCOTT** asked the Minister of Health whether his attention had been called to the circular issued last August by the Board of Control to local authorities under the Mental Deficiency Act, 1913, calling upon them to limit their expenditure under the Act next year to the total amount sanctioned for this year; whether he was aware that, even if no cases except those classed as urgent by the Board of Control were dealt with, the result of the limitation thus imposed would be to leave some 2000 urgent cases uncared for, to their own unhappiness and suffering, to the great harm of many others, and at a cost to the community in rates and taxes for police, criminal justice, and Poor-law many times as great as the cost of looking after them under the Act; and would he consider this question.—Brigadier-General **COLVIN** asked the Secretary to the Treasury whether the Treasury contribution to mental defectives was being withheld from many urgent and dangerous cases, with the result that they are left unrestrained and are a danger to the community; and whether admissions into institutions were limited to a prescribed number.—Sir A. **MOND** replied: I have seen the circular referred to. Local authorities are at present only able to deal with urgent cases, as defined by the Board of Control, provided that the expenditure involved falls within the limits of their approved estimates for 1921–22. The general question of the limitation of expenditure under the Mental Deficiency Acts necessitated by the decision of the Government that the public expenditure must be drastically reduced is receiving careful consideration, and the points mentioned in the questions will be borne in mind.

Scarlet Fever and Diphtheria in London.

Mr. **GILBERT** asked the Minister of Health whether his attention had been called to the increase of scarlet fever and diphtheria cases in London; whether his department had taken any action in order to control the spread of these diseases; if so, in what way; the number of cases now under treatment in hospitals; and if there were a sufficient number of hospital places for all sufferers if the epidemics spread further.—Sir A. **MOND** replied: The answer to the first part of the question is in the affirmative. The answer to the second part is that I have appointed a special office committee with medical representation of the London County Council and the Metropolitan Asylums Board. There are at present 6192 cases of scarlet fever and 2996 cases of diphtheria under treatment in the hospitals of the Metropolitan Asylums Board. The Board's accommodation is limited to approximately 9500 beds, but it is hoped that the arrangements which have now been made will meet the needs of the situation.

The defence sought to prove: 1. That the fracture was diagnosed as one of the upper third of the femur. 2. That the limb was kept abducted during treatment. 3. That the fracture was satisfactorily united without angulation and with only half an inch of shortening at the time plaintiff left Beccles. 4. That the union subsequently gave way because the plaintiff put weight upon it contrary to Dr. Wood-Hill's advice.

Actually the result of the case depended largely upon the question whether a re-fracture had or had not occurred. I was asked whether at the operation I found evidence of re-fracture, and replied that I did not; but I pointed out that the interval between the giving way of the limb and the operation (18 days) was sufficient for signs of re-fracture to have disappeared. Apart from this, both judge and jury seem to have ignored the possibility of bending of the callus, a well-known and common incident in fracture of the femur, which I endeavoured to emphasise in my evidence. Counsel, in summing up, claimed that my evidence negatived re-fracture, and, on the strength of this, the evidence from the Beccles Hospital that the position of the bone was satisfactory when the plaintiff left the hospital was ignored or disbelieved.

Important lessons to be learnt from this case are that every case of fracture or possible fracture should be treated as a possible medico-legal one; that careful notes made at the time should be kept; that if an X ray is not taken, the reason should be stated in writing; and that practitioners should not commit themselves to statements or diagrams of the nature of an injury except on X ray evidence. Apart from this, the medical profession must feel considerable perturbance at a legal decision which appears to place upon them responsibility for the result of their treatment apart from their acknowledged responsibility to use recognised methods and to use them carefully, for it would appear that the mere fact that the result of the treatment of the fracture was unsuccessful was accepted as a sufficient cause of action. This seems to suggest an entirely new aspect of medical responsibility. I am, Sir, yours faithfully,

Portland-place, W., Nov. 21st, 1921. R. C. ELMSLIE.

NOTIFICATION OF TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—I write to support the suggestion of Dr. G. Lissant Cox which appeared in his paper contained in your issue of Nov. 19th to the effect that Article V. of the Public Health (Tuberculosis) Regulations should be amended by the removal of the proviso that a doctor shall not notify a case of tuberculosis if he has reasonable grounds for believing that the case has already been notified in the same district. In an industrial area it is not uncommon for a person to change his doctor. The first doctor may not have quite made up his mind as to the diagnosis, and the second doctor thinks that the first medical attendant has notified. If notification is to be of real value it must be complete, and this is one way to help to make it of real value.—I am, Sir, yours faithfully,

W. ALLEN DALEY,
Nov. 21st, 1921. M.O.H., Blackburn.

THE COCAINE HABIT.

To the Editor of THE LANCET.

SIR,—Some 25 years ago I reported the case which I treated here of a woman, about 35 years of age, moving in very good society in England, who had been taking 2 g.—i.e., 30 gr. of cocaine daily for some years—employing cognac and chloral hydrate as counter-poisons. Her drug bill amounted to over £100 a year. I was able to reduce the amount of cocaine by three-fourths in five weeks. She got rid of the remnant of the habit herself by her resolution and resort to much physical exercise—e.g., bicycling. She told me then that *all* her acquaintances living in London used some such stimulant to "get through the Season," an exaggeration that certainly had some foundation. From what I hear it appears to me necessary to warn the medical profession in England to prescribe cocaine as little as possible, or never. In the case to which I have referred it was ordered for outward application, and obliging chemists all over the world renewed the prescription. The cocaine habit is on the increase here. A few days ago a chemist's shop was broken into in Zurich and among the large store of medicines stolen were cocaine, morphine, veronal, pantopon, opium, and scopolamine. This may repeat itself anywhere unless a close scrutiny is kept over illegal sales of poison.

I am, Sir, yours faithfully,
TH. FINDLATER ZANGGER, M.D.
Zurich, Nov. 18th, 1921.

THE EARLY DISCHARGE OF SCARLET FEVER CASES.

To the Editor of THE LANCET.

SIR,—Referring to the notice of my annual report in your issue of Nov. 5th (p. 978) I beg to say that I claim no priority for my action of dismissing uncomplicated cases of scarlet fever from hospital after a stay therein of less than the orthodox period of six or eight weeks, and as a matter of fact Dr. S. G. Moore has reminded me that he had done this for some time previously with the precaution of using salicylic acid as a disinfectant of the desquamating cuticle; but my investigations, subsequently borne out by practical experience, convinced me that this was not necessary, and that the ordinary precautions generally in vogue are all that is required.

I am, Sir, yours faithfully,
Edinburgh, Nov. 12th, 1921. JAS. T. NEECH.

The Services.

ROYAL ARMY MEDICAL CORPS.

Maj. A. E. Atkinson, late temp. Capt., to be temp. Maj., and to relinquish the rank of Maj.

Capt. C. H. Stringer to be temp. Maj. whilst spec. empld. as D.A.D. of H.

Officers relinquishing their commissions:—Temp. Capt. E. E. Chipp (granted the rank of Maj.). Temp. Capt. J. H. Rodgers (retains the rank of Maj.). Temp. Lts. retaining the rank of Lt.: G. A. Clarkson and J. H. Howitt.

A. James to be temp. Lt. whilst empld. as a Dental Surg.

TERRITORIAL ARMY.

Maj. R. Lindsay, having attained the age limit, is retired and retains the rank of Maj., with permission to wear the prescribed uniform.

Capt. A. R. Paterson, having attained the age limit, is retired and is granted the rank of Maj.

Capt. W. Murray, having attained the age limit, is retired and retains the rank of Capt.

Capt. A. J. A. McCabe-Dallas resigns his commn. and retains the rank of Capt.

Lt. J. G. B. Coleman (late R.A.M.C.) to be Lt.

INDIAN MEDICAL SERVICE.

The King has approved the retirement of Lt.-Cols. C. H. James, D. C. Kemp, and S. B. Smith.

CENTRAL COUNCIL FOR LONDON BLIND.—The London County Council has appointed Capt. O. E. Warburg to be chairman of the newly constituted Central Council. The chairman and vice-chairman of the County Council's Special Committee for the Welfare of the Blind automatically become members of the Central Council. In addition, the County Council has appointed the following six persons with special knowledge of the needs of the blind to be members of the Central Council: Mr. A. E. Barber, Mrs. Adolphus Duncombe, Capt. Ian Fraser, Mrs. W. F. Hamilton, Mr. Henry Stainsby, and Mr. F. G. Mowatt. The President of the Board of Education and the Minister of Health informed the County Council that, while they did not see their way to appoint representatives to serve on the Central Council, they were anxious to render assistance and were willing to allow representatives to attend informally at meetings. Seven associations and institutions have appointed members, and negotiations are proceeding to obtain nominations from the remainder of the 19 associations in London who are concerned with the welfare of the blind.

Cancer Hospital.—The annual dinner will take place at the Hotel Cecil on Thursday, Dec. 8th. The chair will be taken by Sir Charles Ryall. Tickets (price 35*s.* each) may be obtained from Mr. Cecil Rowntree, 9, Upper Brook-street, London, W. 1.

Epsomian Club.—The annual meeting and dinner of the Club will take place in the Oak Room, Trocadero Restaurant, Piccadilly Circus, on Thursday, Dec. 8th: meeting at 6.15 P.M., dinner at 7.15 P.M. (10*s.* 6*d.* without wine). Dr. H. E. Haynes will take the chair. Members of the Club intending to be present will notify the hon. secretary, Dr. S. Maynard Smith, 49, Wimpole-street, London, W. 1.

Medico-Legal Society.—The annual dinner of this society will take place at the Holborn Restaurant on Wednesday, Dec. 14th, at 7.0 for 7.15 o'clock. Tickets, at 14*s.* 6*d.* (exclusive of wine), for members and guests may be obtained from the hon. secretary, Mr. Ernest Goddard, at 3, South-square, Gray's Inn, London, W.C. 1.

Westminster Hospital Students' Union: Guthrie Society.—The programme of meetings of this society, of which Dr. A. S. Woodwark is the president, is as follows: On Dec. 8th a Guthrie Society "Smoker" will be held; on Jan. 12th, 1922, Mr. Alfred H. Tubby will lecture on Some Experiences during the War in the Near East; Feb. 9th will be devoted to a clinical evening, when surgical cases will be shown; on March 9th Capt. A. E. Hayward Pinch will give an illustrated lecture on Radium Therapy; on March 23rd a smoking concert will be held. The meetings will be held at 8.15 P.M. in the board room of the hospital with the exception of the smoking concerts, which will take place at the medical school.

A Christmas carnival and children's fair will be held at Albert Hall from Dec. 26th to Jan. 4th, from 1.30 to 10 P.M., in aid of the following hospitals and institutions: Cheyne Hospital for Children, Church of England Waifs and Strays, City of London Maternity Hospital, East London Hospital for Children, Hospital for Sick Children, Great Ormond-street, Invalid Children's Aid Association, London Lock Hospital (Infants' and Children's Section), National Institute for the Blind, "Sunshine" Homes for Blind Children, Royal Waterloo Hospital for Women and Children, "Save the Children" Fund (British Section), Victoria Hospital for Children. Further particulars can be had from Mrs. Claremont, National Institute for the Blind, 224, Great Portland-street, London, W. 1.

The late Professor Delépine.—At a special meeting of the Senate of the University of Manchester held on Nov. 15th the following resolution was unanimously adopted:—

> The Senate desires to express its deep sorrow at the death of Prof. Sheridan Delépine, and to place on record its high appreciation of the distinguished services he rendered to the University, and to the sciences of pathology, bacteriology, and preventive medicine. During 30 years of strenuous work as a professor of this University he firmly established the position of pathology in the medical school, he made valuable contributions to medical science, and by the unstinted labours which he devoted to the organisation and development of the public health department he conferred lasting benefit upon the community.

Royal Medical Benevolent Fund.—At the meeting of the committee held on Nov. 8th 20 cases were considered, and £262 voted to 18 applicants.

Daughter, aged 64, of M.R.C.S. Eng. who practised at Bideford and died in 1872. Applicant suffers from cerebral hæmorrhage, and a trained nurse is supplied by friends who cannot continue to help indefinitely. She lives in one room lent by a friend. Her total income is derived from a life interest in £750, which amounts to £15 per annum. Voted £10.

F.R.C.S. London and M.D. Brux., aged 49, suffers from epilepsy and is at present in St. Thomas's Hospital. Owing to indifferent health has had no practice for seven years and has taken locums when well enough. His wife's income of £50 per annum is all that they have to depend upon. Voted £26 in 12 instalments.

Widow, aged 67, of L.R.C.P. Edin. who practised in Durham and during the war served as a surgeon on board Elder Dempster Line, and was drowned in a collision crossing to France in 1917. Applicant has been living on a small legacy and £100 granted her by the Elder Dempster Line. These funds are now exhausted and she is now living on proceeds of sale of jewellery and is nearly at the end of her resources. She is willing to take a post to enable her to support herself, but finds her age against her. Rent 8*s.* 6*d.* per week for one room. Voted £18 in 12 instalments.

Daughters, aged 57 and 49, of L.S.A. who practised at Ilford and died in 1903. Owing to ill-health they are unable to support themselves. Their joint income amounts to £82. Relieved by the Fund 13 times, £171, last £18 in 12 instalments, November, 1920, jointly. Voted £18 in 12 instalments.

Widow, aged 58, of M.B. Aberd. who practised at Watlington and died in 1912. All savings were used up in expenses connected with late husband's and daughter's illness, and applicant was left without means and owing to ill-health is unable to work for a living. A sister-in-law allows her 10*s.* per week. Rent 5*s.* per week. Relieved by the Fund six times, £70. Last time November, 1920, £12 in 12 instalments. Voted £18 in 12 instalments.

Widow, aged 65, of M.D. Glasg. who practised in Downe and died in 1907. The two elder sons are married and unable to help their mother: the youngest died on active service. The War Office allows applicant a pension of 14*s.* per week. Owing to defective eyesight is now unable to earn anything by sewing, and her only other income is derived as follows: £12 10*s.* per annum from investments and 14*s.* per week from a lodger. The rent and taxes amount to £42 per annum. Relieved by Fund seven times, £64, last £12 in 12 instalments, November, 1920. Voted £12 in 12 instalments.

Widow, aged 40, of L.R.C.P. Edin. who practised in Edinburgh and died in 1916. Applicant was left with four children, with an income of about £95 per annum: the children's ages now range from 7 to 15 years and they are all at school. Apart from the £95, she received this year £7 10*s.* towards education and £48 from a lodger. Rent and rates £53 per annum. Relieved by the Fund five times, last £18 in 12 instalments, November, 1920. Voted £18 in 12 instalments.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters J. Symonds, at 11, Chandos-street, Cavendish-square, London, W. 1.

R.M.B.F., War Emergency Fund.—A general meeting of the members of this Fund will be held at 11, Chandos-street, London, W., at 5 P.M., on Wednesday, Dec. 7th, when a report of the work of the Fund since its inception in 1916 will be presented and an outline given of the scope for its usefulness in the next few years.

Molteno Institute for Research in Parasitology.—This institute is to be opened by Lord Buxton at Cambridge on Monday, Nov. 28th, at 3 P.M. As we have already announced, the new institute is a gift to the University of Cambridge from Mr. and Mrs. Percy A. Molteno.

Society of Superintendents of Tuberculosis Institutions.—A general meeting of this Society will be held at 122, Harley-street, London, W., on Monday, Dec. 5th, at 4 P.M., when the Place of the Colony in the Tuberculosis Scheme will be discussed.

London Homœopathic Hospital.—The Countess of Plymouth presided at the Pound Day, promoted by the Ladies' Guild on Tuesday, Nov. 22nd, when the hospital benefited by the receipt of 820 lb. in goods and £107 in monetary contributions.

Foreign Decorations.—The Cross of Chevalier of the Order of Leopold has been conferred upon Dr. S. J. Gilfillan, and the Cross of Commander of the Order of the Crown of Italy upon Dr. H. W. Kaye, for valuable services rendered by them during the war.

The late Dr. William Howard Edwards.—Dr. Edwards, who died at a nursing home at Bletchingley, Surrey, on Nov. 13th, qualified M.R.C.S., L.R.C.P. Lond. in 1899, after studying medicine at Guy's Hospital, where he afterwards held a house appointment. He was a well-known medical practitioner in Streatham and the surrounding districts, and in addition to being medical officer to several insurance societies was honorary physician to the Rochester Diocesan Lodge, Brixton.

Leeds and West Riding Medico-Chirurgical Society.—A meeting of this society was held on Oct. 28th. Amongst numerous specimens and cases exhibited by members Dr. Maxwell Telling and Sir Berkeley Moynihan showed a patient suffering from long-standing acholuric jaundice in whom splenectomy had been performed. Dr. Telling read a paper entitled Psychotherapy with and without Specialism. An animated discussion followed.

At a meeting held on Nov. 11th at the Leeds General Infirmary operations were performed and cases demonstrated by members of the honorary staff. This type of meeting was a new departure undertaken at the request of a number of members.

West Kent Medico-Chirurgical Society.—A meeting of this society was held on Nov. 11th at the Miller General Hospital, Greenwich, when Mr. P. B. Roth read a paper on the Treatment of Fractures. He showed X ray plates and photographs of his cases, and urged that X ray photographs in two planes should be taken when there was injury of bones and joints; screening was not sufficient. His treatment of fracture of the clavicle was a fortnight in bed, flat on the back, without a pillow. After this treatment, he said, no deformity remained, whereas Sayer's method left a deformity and sometimes a paralysis of the hand. He advised the gentle stroking advocated by Lucas-Championnière instead of ordinary massage, and said that function returned early under this treatment. Tying the wrist to the opposite side of the neck was good treatment for fractures of the upper extremity. According to Mr. Roth, the less splinting used in fractures the better. In Colles's fracture, he said, the wrist must be kept flexed. Fractures of the femur required plate and screws to prevent deformity and loss of function; simple wiring of the broken ends of a long bone was not sufficient.

of the qualifying examinations held in this country had just been completed, the reports being in the hands of the members of the Council. On these and on any general conclusions regarding medical education the Examination Committee of the Council would report.

The inspection of the numerous examinations for

Diplomas and Degrees in Public Health

has been carried out, and concerning these post-graduate qualifications, for which the Council has a direct and special responsibility, the President said:

"The Diploma purports to guarantee that the holder possesses an expert knowledge of State Medicine, that he is highly proficient in all the branches of knowledge, scientific and practical, that concern the public health, and that he is fit to hold the administrative position and exercise the statutory functions of a medical officer of health. The rapid growth in the number and importance of these functions makes it necessary that the Council should from time to time revise the conditions it prescribes for the training and examination of such medical officers. It may find that certain subjects have become less necessary than of old, while other subjects, not heretofore greatly regarded, have become important for full efficiency. The weighty and well-considered general report of our inspector, Dr. Bruce Low, in which he sums up the lessons of his observations, deserves the Council's careful attention from this point of view. It would appear that for the modern Public Health Service the qualification to be required before admission to office should be more than an academic certificate, attainable after nine months or so of additional study, by a licentiate or graduate who has just obtained his first licence to practise. It should imply a greater maturity of outlook, a deeper knowledge of principles, and a fuller practical acquaintance with actual administrative methods than an inexperienced practitioner can fairly be expected to compass in a year. Something equivalent to a short apprenticeship in a working Public Health Department is in fact needed to supplement the lectures and demonstrations of the class-room and laboratory. The Public Health Committee of the Council, impressed by these considerations, has after full discussion prepared a series of Recommendations in this general sense. These, if they should meet with your approval, will have the effect of rendering the Council's rules simpler in expression and more uniform in operation, and of ensuring a greater maturity and a higher level of practical efficiency in those who propose to devote themselves as administrative specialists to the Public Health Service."

A Heavy Programme.

The President announced an invitation from the Revision Committee of the Pharmacopœia of the United States to coöperate with the Pharmacopœia Committee of the General Medical Council in the solution of problems of common interest, and concluded his address by stating that many matters of importance had been placed on the programme for the session, making it likely that the Council would have to sit throughout the week. Four disciplinary cases will be dealt with during the session, some of them suggesting that the extreme importance of the issue of correct medical certificates is not sufficiently recognised by the profession at large.

THE Duke of York has accepted the office of President of the Corporation of the Seamen's Hospital Society (Dreadnought), Greenwich.

HERBERT CHARLES WILKIN, M.R.C.S., L.S.A.: A VETERAN.—A very old member of the profession died on Nov. 11th in the person of Dr. Wilkin. He was born on Oct. 6th, 1832, and was thus in his ninetieth year. The son of Henry Wilkin, surgeon, of Connaught-terrace, W., he was educated at Mitcham Grammar School and came up to St. George's Hospital in September, 1852. He took the ordinary double qualification of his day, the M.R.C.S., L.S.A. in 1855, and proceeded to the Crimea as surgeon to the transport ship *Argo*; later he became assistant surgeon, 3rd Royal Surrey Militia, and settling in the Paddington district he acted as consulting surgeon to the Paddington Maternity and Rounhams Convalescent Home; he was also a member of the Harveian and Pathological Societies. In Paddington and in harness he continued to the end of his long life. In an interesting letter written to the Dean of St. George's Hospital in September of this year, he stated that he was dresser at the hospital to Mr. Cæsar Hawkins and clerk to Dr. Bence-Jones, and that the late Mr. Timothy Holmes was the house surgeon. He died at 27, Aldridge Park Villas, Westbourne Park, where he was in practice.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Pharmacy Acts Amendment Bill.

MR. O'GRADY, supported by MR. WATTS MORGAN and MR. CASEY, have introduced into the House of Commons a Pharmacy Acts Amendment Bill "to regularise the position of all persons trading as chemists and druggists or pharmacy store proprietors in the sale of drugs, the dispensing of doctors' prescriptions, and the sale of patent medicines." The Bill was formally read a first time before the prorogation, but time prevented it being proceeded with further till next session. The measure consists of 16 clauses. In Clause 1 it is proposed to enact that on and after Jan. 1st, 1925, no person shall be entitled to assume or use the title chemist in any part of Great Britain, without prejudice to his right to assume or use any other title mentioned in the Pharmacy Acts, unless such person shall be a chemist within the meaning of this Act, and be registered under this Act, provided that any person now entitled to describe himself as a chemist and druggist, or druggist, or pharmacist, or dispensing chemist or druggist, shall continue to be entitled to use so much of such title as does not include the word "chemist." Clause 2 states that on and after Jan. 1st, 1925, the Incorporated Society of the Institute of Chemistry shall alone possess the power to authorise any person to assume or use the title "chemist," and the Incorporated Society of the Institute of Chemistry shall from time to time appoint competent persons to conduct examinations for the purpose of granting persons permission or authorising persons to assume or use the title "chemist," and every person who shall have been examined by such examiners and shall have obtained from them a certificate of competent skill, knowledge, and qualification shall be entitled to register as a "chemist" under this Act, and no person shall conduct any examination until his appointment has been approved by the Privy Council, and such appointment and approval shall not, in any case, be in force for more than five years. Clause 3 provides that the registrar under the Pharmacy Acts shall place upon the Pharmaceutical Register (1) all persons who have satisfied the Council of the Incorporated Society of Pharmacy and Drug Store Proprietors of Great Britain, Limited (herein called the Pharmacy Society), at any time before and including the thirty-first day of December nineteen hundred and twenty-four, and being members of the Pharmacy Society, of their fitness to be placed upon the register, and (2) after the first day of January nineteen hundred and twenty-five, any person, being a member of the Pharmacy Society or not, who so satisfies the Pharmacy Society and in addition has received a certificate from a qualified medical practitioner, in the case of a person carrying on business in boroughs and urban districts, and of two qualified medical practitioners, in other places, that such person, to his or their knowledge has carried on business as a pharmaceutical proprietor on his own account for a period of not less than five years, and is personally known to such qualified medical practitioner or medical practitioners making such certificate to be a person of good repute and competent to carry on business as a pharmaceutical proprietor. Clause 4 gives to the Pharmacy Society similar powers to conduct examinations authorising persons to be placed on the Pharmaceutical Register as are given under Clause 2 to the Incorporated Society of the Institute of Chemistry. Clause 5 constitutes a Central Council consisting of 16 members, of whom four shall be appointed by the British Medical Association, four by the Incorporated Society of the Institute of Chemistry, four by the Pharmaceutical Society, and four by the Incorporated Society of Pharmacy and Drug Store Proprietors of Great Britain, Limited, together with a chairman who shall be appointed by and be a member of the Privy Council. Clause 6 provides for the holding of examinations by the Central Council biennially at London, Leeds, Birmingham, and Edinburgh. Under Clause 7 persons below the age of 21 years are prohibited from carrying on the business of pharmacy.

Clauses 8 and 9 deal with the sale of poisons. By Clause 8 it is proposed to enact that in addition to any conditions now contained in any Act of Parliament the following provisions shall have effect: (*a*) So far as regards such poisons and poisonous preparations or compounds thereof as may be sold only on the production of a medical practitioner's prescription or order, a copy of such prescription or order must be duly entered by the registered pharmacist in a special book for the purpose, and the prescription must be duly signed with the name and address and academic qualifications of such medical practitioner, and no such prescription or order shall be repeated without a further prescription or order being provided; (*b*) as regards such poisons as may be supplied by a registered pharmacist

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.

TUESDAY, Nov. 29th.—4.30 P.M., Mr. H. H. Rayner: Cancer of the Breast; Early Diagnosis and Results of Treatment.

MANCHESTER FRENCH HOSPITAL POST-GRADUATE LECTURES, 21, Acomb-street, Whitworth Park.

THURSDAY, Dec. 1st.—Dr. A. C. Magian: The Menarche and Menacme.

Durham, Richard Murray Hospital, Blackhill.—Res. M.O. £100.
Frimley, Burrow Hill Sanatorium, &c.—Res. Med. Supt. £600.
Fulham Parish Infirmary, St. Dunstan's-road, Hammersmith.—Third Asst. M.O. £300.
General Lying-in Hospital, Lambeth.—Res. M.O. £100.
Greenwich, Dreadnought Hospital.—H.S. £150.
Guildford, Royal Surrey County Hospital.—H.S. £150.
Hove Hospital.—Res. M.O. £250.
Iraq.—Two M.O.'s. 600 to 1000 rupees per mensem.
Lincoln County Hospital.—Jun. H.S. £150.
London Homœopathic Hospital, Great Ormond-street.—Third Anæsth. £50.
London Hospital, Mile End.—Asst. S.
London Temperance Hospital, Hampstead-road.—Res. Cas. O. £150.
Manchester Royal Infirmary.—Asst. M.O. and Asst. Surg. O. Each £35.
Manchester, Salford Royal Hospital.—Hon. Asst. Radiologist.
Middlesex Hospital.—Asst. Radiologists and Asst. Electro-Physio-Therapeutist. £200 each.
Newport, Mon., Royal Gwent Hospital.—H.S. £200.
Norwood Cottage Hospital.—Two vacancies on Hon. Med. Staff.
Nottingham Children's Hospital.—Female Res. H.S. £180.
Oldham Royal Infirmary.—Three H.S.'s. Each £200.
Prince of Wales's General Hospital, Tottenham.—Hon. Surg. Reg. £100.
Rochdale Infirmary and Dispensary.—Jun. H.S. £200.
Rochester, St. Bartholomew's Hospital.—Res. H.P. £200.
Royal Free Hospital, Gray's Inn-road, W.C.—H.S. and Sen. Obstet. Asst. Clin. Assts.
Royal National Orthopædic Hospital, Great Portland-street.—H.S. £150.
Royal Naval Medical Service.—Surg. Lieuts.
Royal Waterloo Hospital for Children and Women, Waterloo-road.—H.P. £100.
Shanghai Municipal Council.—Asst. Health Officer. £1540.
Sheffield, Jessop Hospital for Women.—Asst. H.S. £100.
Sheffield Royal Infirmary.—H.P. and Asst. Cas. O. £150.
South-Eastern Hospital for Children, Sydenham.—Res. M.O. £100.
South Mimms, Clare Hall Sanatorium.—Asst. M.O. £350.
Southport General Infirmary.—Jun. H.S. £175.
Sunderland, Children's Hospital.—Female Jun. Res. M.O. £150.
Ventnor, Royal National Hospital for Consumption.—Asst. Res. M.O. £300.
Walsall Education Committee.—School Med. Insp. £500.
Warrington, Lancashire County Asylum, Winwick.—Asst. M.O. £300.
West London Hospital, Hammersmith-road.—Two H.P.'s and one H.S. Each £100.
West Riding County Council.—School Oculist. £600.
Willesden Hospital, Harlesden-road.—Hon. Anæsth. and two Hon. Dent. Surgs.
Worcester County and City Mental Hospital.—Sen. Asst. M.O. £500.

The Chief Inspector of Factories, Home Office, S.W., announces the following vacant appointments: Newton Abbot (Devon), and Cardigan.

The Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the Preston and Chorley and Lancaster County Courts. Applications should reach the Private Secretary, Home Office, not later than the 14th December.

Births, Marriages, and Deaths.

BIRTHS.

BRADFIELD.—On November 1st, at Moorats Gardens, Madras, the wife of Major E. W. C. Bradfield, I.M.S., of a daughter.

EDEN.—On Nov. 14th, at a nursing home, Edgbaston, the wife of Geoffrey Eden, M.D., M.R.C.P., of a son.

MATTHEWS.—On Nov. 19th., at Eversfield-place, St. Leonards-on-Sea, the wife of L. Clive Matthews, L.D.S. R.C.S.Eng., of a son.

MARRIAGES.

FINDLAY—DAY.—On Nov. 17th, at the Church of the English Martyrs, Streatham, S.W., John Findlay, M.D., D.P.H., to Winifred Marie, youngest daughter of Mr. John T. and Mrs. Day, Hayeswood, Streatham Park, S.W.

YOUNG—GOULD-TAYLOR.—On Nov. 11th, at Consulate, Port Said, and Nov. 12th, at St. Andrew's Church, Cairo, Peter Hutchison Young, M.B., Ch.B., R.A.F. Medical Service, to Sheila, younger daughter of the late Rev. N. Gould-Taylor and Mrs. Gould-Taylor, Melbourne, Australia.

DEATHS.

LE QUESNE.—On Nov. 18th, at Southampton, Claude Philip Le Quesne, M.R.C.S., L.R.C.P., aged 55 years.

MERRALL.—On Nov. 16th, at 26, North Promenade, St. Annes-on-the-Sea, Mary Topping, the beloved wife of Harry Merrall, M.B.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Ex-Service Men in Lunatic Asylums.

Captain LOSEBY asked the Prime Minister (1) if he was aware that treatment allowances upon which some 6000 ex-Servicemen depended were paid strictly upon the condition that these men consented to being confined in lunatic asylums, whereas the allowance was refused in respect of patients being treated, and anxious to be treated, in certain private institutions approved by the Board of Control, but to which the stigma associated with lunatic asylums was not attached; and why the allowance was not paid in the latter class of cases. (2) If, according to official figures, on Jan. 1st, 1919, 2507 ex-soldiers were confined in lunatic asylums; that the figure had risen to 4673 on Jan. 1st, 1921, and to 6435 on Oct. 27th, 1921; if he was aware that bitter laments were continually emerging from the men so confined; and if, in view of the increase in the number of men so confined, he would consider the advisability of setting up a commission comprised of Members of the Houses of Parliament to hear complaints and investigate any possible amelioration of the conditions governing the detention of these men.—Mr. MACPHERSON replied: The Lunacy Law requires that every person who is certified as insane shall be sent to an institution approved by the Board of Control; save that under certain conditions a single patient may be placed in a private house not specifically licenced for the reception of lunatics. Treatment allowances are granted and the necessary cost of treatment defrayed by my Department in respect of all certified patients whose insanity is due to war service and who are receiving treatment in institutions, whether public or private, which have been approved by the Board of Control and by the Ministry. I cannot, of course, speak for the ex-Service men in asylums, the origin of whose unfortunate condition does not entitle them to the benefits of the Royal warrant, but as regards certified "Service" patients it is certainly not accurate to suggest that any large number of complaints are received as to the conditions of their treatment. On the contrary, the number of complaints received is few, and, on investigation, they have invariably proved to have been made on unsubstantial grounds, or to have been of minor importance. When a complaint is made it is the practice for the institution to be inspected and the whole circumstances investigated by officers of my Department either alone or jointly with commissioners of the Board of Control. Perhaps I may inform my hon. friend and the House generally that under an arrangement with the Board of Control, asylums are now visited by medical inspectors of my Department and the Service patients personally interviewed. By these means I am kept in close touch with the conditions of asylums, and I do not consider that there is any ground for adopting my hon. friend's suggestion to set up a commission of the House. I may add that I do not accept my hon. friend's statement of the numbers of ex-soldiers in asylums in January, 1919, and January, 1920, as accurate. At the latter date the number of certified Service patients was approximately 6000.

Treatment of Tuberculous Ex-Service Men.

Dr. M'DONALD asked the Minister of Pensions if he would take steps to relax the order that tuberculous ex-Service men must be treated within the area of their residence, especially when greater benefits could be offered outside such area and voluntary means were available for the maintenance of the patient.—Sir A. MOND (Minister of Health) replied: So far as I am aware no such order as is referred to in the question has been issued. The institutional treatment of tuberculous ex-Service men is undertaken by the county and county borough councils, and it is within the discretion of a council acting on the advice of their tuberculosis officer to decide in what institution any particular case shall be treated, provided that the institution and the arrangements made by the council for the use of the particular institution have been approved by the Ministry of Health.

Motor Taxation.

Major BARNES asked the Minister of Transport what was the amount which had been collected up to date in motor taxation; what amount from this had been allocated to local bodies; what amount had been paid out of this to highway authorities; what amount had been allocated in loans; and, when repayments were made, what happened to the money so returned.—Mr. NEAL (Parliamentary Secretary to the Ministry of Transport) replied: The total proceeds from the motor taxation to Oct. 31st, 1921, are £10,437,907 2*s.* 6*d.* The whole of this amount, less statutory deductions, has been paid to the road fund and has been allocated to road works, and in the main to local authorities. All payments (including advances by way of loan) are made out of the road fund generally, and not out of particular collections. All sums received by way of repayment of loans or by way of interest are credited to the local fund.

Medical News.

UNIVERSITY OF LONDON.—At examinations held recently the following candidates were successful:—

THIRD (M.B., B.S.) EXAMINATION FOR MEDICAL DEGREES.

Dulcie S. Adkins, London Sch. of Med. for Women; John S. Alexander, Univ. Coll. Hosp.; Frances S. Barry (honours, distinguished in midwifery) and Geraldine M. Barry (honours, distinguished in medicine and midwifery, University medal), London Sch. of Med. for Women; George O. Berg and Percy C. Brett, St. Thomas's Hosp.; William M. Brown, Guy's Hosp.; John D. M. Cardell, St. Thomas's Hosp.; Dorothy S. Chamberlain, King's Coll. Hosp.; Cecil S. Cloake, London Hosp.; Ivy Collier, St. Mary's Hosp.; Philip N. Cook, St. Bart.'s Hosp.; Barbara Cubitt, London Sch. of Med. for Women; Charles O. Davies (honours, distinguished in forensic medicine), Liverpool University; George Day, St. Bart.'s Hosp.; Edith M. Down, London Sch. of Med. for Women; Ronald B. Green, Univ. Coll. Hosp.; Eleanor Harse, London Sch. of Med. for Women; Martin C. Hartley (honours, distinguished in forensic medicine), London Hosp.; Reginald W. P. Hosford, St. Bart.'s Hosp.; Arthur St. G. J. M. Huggett, St. Thomas's Hosp.; Bryan L. Jeaffreson, St. Bart.'s Hosp.; Marjorie M. Jefferson, Manchester University; Doris E. P. Jolly, King's Coll. Hosp.; Henry C. V. Joy (honours, distinguished in surgery), London Hosp.; Allan N. Kingsbury, Middlesex Hosp.; Anna G. M. Lewis, Univ. Coll. Hosp.; David J. A. Lewis, London Hosp.; Ivor Lewis and Kingsley W. Lewis, Univ. Coll. Hosp.; David M. Lloyd-Jones (honours, distinguished in medicine), St. Bart.'s Hosp.; Iorwerth H. Lloyd-Williams, Middlesex Hosp.; Muriel J. Lough, St. Mary's Hosp.; Alan McKenzie, Guy's Hosp.; Dorothy McNair, London Sch. of Med. for Women; John A. W. Robinson, King's Coll. Hosp.; Samuel Rose, Guy's Hosp.; Maud Sanderson (honours, distinguished in medicine) and Ruth M. Scutt, St. Mary's Hosp.; William H. Simmons, Guy's Hosp.; John E. Stacey, Sheffield University; Kathleen A. H. Sykes (honours, distinguished in surgery), Liverpool University and London Sch. of Med. for Women; Eric W. C. Thomas (honours, distinguished in forensic medicine and surgery), St. Bart.'s Hosp.; Ruth C. Townshend, Norah Tregear, and Doris L. Veale, London Sch. of Med. for Women; Gladys M. Wauhope, St. Andrews University and London Hosp.; and Keith M. C. Woodruff, Guy's Hosp.

ROYAL COLLEGE OF SURGEONS OF ENGLAND: ANNUAL MEETING OF FELLOWS AND MEMBERS.—On Nov. 17th Sir Anthony Bowlby, the President of the College, attended to preside at this meeting at 3 P.M. in the College theatre. As it was found that there were not a sufficient number present to form a quorum at 3.15 P.M. the President announced that according to the rules no meeting could take place. The President therefore retired. A protest was made by certain Fellows and Members who were present, and an informal meeting took place at which the resolutions on the agenda in favour of the admission of Members of the College to the Council of the College were passed.

ROYAL COLLEGE OF SURGEONS IN IRELAND.—On Nov. 19th, in the absence of the President through illness, the Vice-President, Sir W. I. de C. Wheeler, distributed the prizes and medals to successful students. In his presidential address he referred to possible changes in the medical curriculum in the near future, and to the need for more practical work in proportion to mere study of books. He advised all young surgeons to travel in order to become familiar with work elsewhere.

HARVEIAN SOCIETY.—A meeting of this society will be held at the rooms of the Medical Society, Chandos-street, Cavendish-square, London, W., on Thursday, Dec. 8th, at 8.30 P.M., when a discussion on Is the Anginal Syndrome only of Cardiac Origin? will be opened by Sir John Charlton Briscoe, followed by Sir Sydney Russell-Wells, Dr. G. H. Hunt, and Sir William Willcox.

HARROGATE MEDICAL SOCIETY.—The fourth meeting of the session was held on Nov. 17th. Dr. A. Mantle presided and there was a good attendance of members. A paper dealing with the Clinical Interpretation of the Wassermann Reaction was read by Dr. F. B. Smith. The importance of the standardisation of the technique was emphasised as well as the desirability of using two antigens. Dr. Smith was of the opinion that cases of doubtful lues giving a negative W.R. should be retested after a provocative dose of an arsenical compound. The anomalies in pregnant women and infants of syphilitic mothers were discussed. Emphasis was laid on the necessity for treatment of syphilis in its earliest stage if relapses were to be avoided. Dr. Smith referred to evidence he had obtained of the thermolabile nature of the reaction in treated cases. The significance of the reaction in the cerebro-spinal fluid was described, and the paper concluded with a few details for obtaining a satisfactory specimen of serum.

this is not governed by the mere size of the glucose molecule is evident when we go to the kidney, for in health the renal cells are also impermeable to glucose, and it is not until normal conditions are upset in diabetes that the kidney cells allow this sugar to pass into the urine. Nevertheless, sugars with larger molecules, such as cane sugar or lactose, if introduced into the blood stream find their way out into the urine even in health. The sieve theory will thus not hold here, so recourse must be had to the "lock and key" hypothesis introduced by Emil Fischer to help us to understand the specific action of enzymes, and which has proved so useful also when one has to deal with questions of specificity in antitoxic and analogous phenomena. The chemical configuration of sucrose is such that it fits the molecular structure of the parts of the cell it penetrates; it can unlock the door and get through; glucose has a different configuration; it cannot open the door so long as the barrier or lock remains healthy. I have taken this to illustrate one of the many features of physiological advance in knowledge, which is of intimate importance to pathology, but even here, after a certain point it is necessary to have recourse to a theory or a useful simile.

Hormones.

There are many other examples of physiological advance I am tempted to press upon you, but I will be content with only one more—that of the chemical messengers or hormones, of which the discovery has been of incalculable benefit to the practitioner. Organs formerly mysterious are now opened books, and the part played by the substances they pour into the blood to minister to parts elsewhere has shed a light on many obscure maladies, as well as on the processes of the healthy body. It is true we have a general conception of the way the endocrine organs work and of what happens when the work is badly done, but up to the present there are only two of these hormones which are known to us in the true chemical sense—to wit, adrenaline, the secretion of the suprarenal medulla, and thyroxin, the iodine complex secreted by the thyroid. True, the discovery of adrenaline was no mean feat and has provided us with a useful drug. When the internal secretion of the adrenal cortex is discovered one may anticipate rational and successful treatment of Addison's disease.

It is necessary to blend newly acquired knowledge with the saving virtue of common-sense. The premature assumption of the truth of various theories is not only inimical to the progress of the science of medicine but may be an actual danger to the community of patients. What cruelly false hopes were raised in the breasts of sufferers when, in the early days of radiology, radium was vaunted as the cure for all or nearly all of our ills, cancer included.

Psycho-Analysis and Spiritualism.

This special evil of the unwisdom of accepting unproved theories, or partially tested cures, is most pronounced when one has to deal with a subject on which our knowledge is scantiest—namely, the action of the mind. I have neither friends nor enemies among the psycho-analysts, so that what I am saying now is entirely impersonal. When speaking of psycho-analysis to medical men I have sometimes been answered in this way. "After all, there are some good psycho-analysts; Dr. So-and-So, for example, gains the confidence of his patients, gives them good advice, and comforts them; he even knows a little neurology." Is not this damning him with faint praise? Any good doctor, psycho-analyst or not, can win, or should win, his patients' confidence and thus benefit them.

Whatever view one may hold as to the value of psycho-analysis in the treatment of so-called functional disorders, there can be no difference of opinion that any attempt to attack organic disease by its agency should at once be authoritatively condemned. Yet I see in an American journal of repute an attempt in this direction on the part of a qualified doctor of medicine; he proposes that multiple sclerosis should be so treated. At first one took the article to be satirical, but it is quite evident that it is intended seriously. In all ages we see at intervals instances of charlatanism making inroads into the region of exact knowledge and delaying its progress. The war has been blamed for present tendencies in this direction; the war may have exacerbated the condition of mental unrest, but did not cause it. To condemn spiritualism with its many ramifications as a delusion or as humbug, and its professors as deceivers or deceived, may be correct, but it is not argument. I should like to see the appointment of a responsible committee made up of physiologists, medical men, physicists, professional conjurers, the spiritualists themselves, together with a certain number of unbiassed public men gifted with common-sense, to investigate it by the cold light of exact experiment, and to report upon the claims of the occultists. As the matter stands at present, the practices of believers in the supernatural can only exaggerate the mental unrest to which I have alluded; moreover, if the statements of one party are ignored, many will conclude that the other side has nothing to say—as they concluded in the anti-vivisection controversy.

In conclusion, progress in the scientific foundation of medicine depends on accurate observation, experiment, and reasoning combined with imagination which must not be unbridled. True knowledge and understanding suffer from the absence of one or more of these essential attributes of progress. To recognise and guard against the pitfalls of half-knowledge is the only way to avoid them.

INSTITUTIONAL CONVALESCENCE.

IN a pamphlet entitled "Convalescent Care for an American City of One Million Population" and reprinted by permission of the Cleveland Hospital Council, Dr. Frederic Brush (Medical Director, the Burke Foundation, White Plains, N.Y.) sets forth a scheme for utilisation of that period of convalescent when recuperative rest may be favourably combined with mental and moral rehabilitation of the patient. Dr. Brush begins with the statement that the patient's home is usually the best place for convalescence, but that institutional accommodation is necessary in a proportion of cases; this proportion he sets at 10 per cent. of all hospital cases, with an additional fifth of that 10 per cent. to include patients from dispensaries and other sources. Assuming the city in question to present fair living conditions, a figure of 5000 hospital patients, plus 1000 from other sources, is taken as a planning basis. The average stay in American convalescent homes has been proved to be about 21 days; thus the 6000 patients require 350 beds.

Allotment of Beds.

An estimate based upon the experience of the institutions in great cities apportions beds as follows: (1) In a main institution for adult men and women of all ages from 15 upwards, 120 beds, including 15 per cent. or more cases of heart disease, together with cases undergoing preventive treatment, standard surgical cases requiring dressings, and cases of "chronic handicapped" convalescence; (2) in a children's home, 100 beds, for girls aged 6–15, and boys aged 6–10, including orthopædic and surgical dressing cases, and heart disease up to 20 per cent. of the total, with the above-named "standard lines" in addition; (3) in a boy's place, 30 beds, for ages 10–15, with disease classification as in the children's home; (4) in a section for mothers with infants and young children, 30 adult beds, averaging 60 patients; (5) in a special heart institution, for the seriously-ill but probably restorable cases, 40 beds, for ages and sexes as in the children's home.

The Cost of Housing.

New or expensive buildings are described as inessential. An old mansion, a large farmhouse with out-buildings, or a disused hotel may readily be adapted. Tents will serve on occasion; extensions are easily made and much equipment may be improvised. Five acres of land is the minimum. The various homes might occupy one large plot of 100 acres if the necessary separation of patients could be ensured. A site within 20 miles of the centre of the city is desirable for purposes of transport, coöperation of staff, &c. A daily cost of $1·75 to $2·00 per head might be expected, giving approximately $225,000 as a minimum yearly working cost for the 350 beds, including transport and maintenance of a city admission office. The selection of patients would be performed by one (possibly part-time) city officer, and the necessary work of following up of cases, including vocational and occupational direction, might be done by the city organisations which sent patients.

Some Details.

Dr. Brush explains that preventive tuberculosis, convalescent orthopædics, and bone diseases are included under (1), (2), and (3) above; that cardiac children well enough for reconstructive graduated exercise treatment are provided for under numbers (2) and (3); that adolescents (the group most successfully dealt with and yet most neglected in convalescence) are especially considered.

"As interest grows," he writes, "and convalescent experience matures, the extensions of this service . . . . will probably be towards separate provision for orthopædics, pay convalescents, the coloured, and for the various border-line, nervous, and mental patients, who everywhere lack long-term preventive and convalescent opportunity."

"Prevention, education, refinement, and Americanisation, occupational adjustment, vocational direction, re-encouragement," are stated to be the objects of Dr. Brush's system. "Such an institution . . . . would serve to stimulate medical study of convalescence, now a field much neglected, and would promote throughout the community interest in the problem of convalescence which will add to the efficiency of all kinds of medical care in hospitals, dispensaries, and in the home."

THE LATE MR. WILLIAM STOKER, F.R.C.S.I.—The death of Mr. W. Stoker, senior surgeon to Jervis-street Hospital, Dublin, and senior member of the Council of the Royal College of Surgeons in Ireland, has recently taken place. Although in his seventy-ninth year he was in active work until within a few weeks of his death. Mr. Stoker received his education in Trinity College and the Royal College of Surgeons in Ireland, and was admitted a Fellow of that College in 1873. Having held the post of lecturer in surgery in the Ledwich School of Medicine from 1881 to 1889, on the amalgamation of that school with the school of the College of Surgeons, he became professor of surgery in the College, and occupied this chair until 1911. Mr. Stoker was a member of the Council of the College from 1882 until his death. In his younger professional days Mr. Stoker was a very successful private teacher, and there were few Dublin students in the 'seventies and early 'eighties who did not pass through his hands. He was held in warm regard by his professional colleagues. His death closes a family connexion with Dublin medicine lasting through three generations.

PROFESSIONAL CLASSES AID COUNCIL.—The Professional Classes War Relief Council, which rendered such valuable service to the new poor during the war, continues its activities under the new title of "The Professional Classes Aid Council." It may be recalled that during six and a half years 12,000 applications were investigated and dealt with by the Council; in the four and a half years when the Council's maternity home in Princes Gate was open 547 babies were born there, of which only two died within the first four weeks of life. The education of 885 children was assisted between November, 1914, and March, 1921, and the help continued in some cases for four or five years; the total sum expended on schooling in six and a half years was £34,000. The Music in War-time Committee of the Council found employment for several hundred musicians, whilst benefiting hospitals and other institutions where entertainments were welcomed. It is not intended that the Council as newly constituted should supplant any benevolent fund organised to deal with a particular profession. Instances, however, arise in which the Council can usefully coöperate with a body unable itself to render the precise kind of help required. Thus, assistance with school fees is still continued, being a very effective method of help. Among the professions which have been or are being assisted are included: Actors, architects and surveyors, artists, authors and journalists, barristers and solicitors, Civil servants, doctors, engineers, members of the Stock Exchange, ministers of religion, musicians, schoolmasters, teachers, and governesses. The Council prides itself on the maintenance of a scrupulous regard for the feelings of applicants. The offices of the Council are now at 251, Brompton-road, S.W. 3.

MR. EMIL COUÉ'S VISIT.—On the invitation of a committee largely composed of British medical men, Mr. Emil Coué delivered on Nov. 18th and 21st at Essex Hall, London, a series of lectures on auto-suggestion based upon his experience as founder and director of the new Nancy School of Applied Psychology. Dr. Burnett Rae, who presided on Nov. 21st, said that while the lecturer had not actually taught psychologists anything new he had impressed upon them the reality of auto-suggestion by relieving many patients, while his teaching was in no way antagonistic to the principles of medical treatment. Mr. Coué explained that he himself did not heal; he taught patients how to heal themselves. Every morning before rising, and preferably before being fully awake, the patient was taught to close his eyes and repeat quietly 20 times or so, moving the lips for emphasis, "Day by day, in all respects, I am getting better and better." The same words were repeated every night on getting into bed. The words "in all respects" made the suggestive words universally applicable. Every time physical or mental discomfort was felt the phrase was repeated. The results were sure, but confidence and faith were necessary. Giving as an illustration the ease with which a man could walk on a plank placed on the ground and the impossibility, in the majority of cases, of doing so when the plank was suspended at a height, the lecturer said that it was the imagination and not the will which permitted the ability and caused the disability; man, he said, would only cease to be a puppet when he learned to control his imagination. The essential thing in practising auto-suggestion was to keep the will from being a hindrance, for if it was not in agreement with imagination it would have the effect of reversing the desired results. The lecturer expressed the hope that the study of suggestion would be introduced into the medical curriculum, pointing out the advantage to the community if backward and mentally deficient children were treated by the method he advocated. The same methods might also be applied to the inmates of reformatories.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, Nov. 28th.

OCCASIONAL LECTURE: at 5 P.M.
Dr. Guelpa (of Paris): The Treatment of Diabetes and Gout by Disintoxication.

MEETINGS OF SECTIONS.

Monday, Nov. 28th.

ODONTOLOGY: at 8 P.M.
Casual Communication:
Mr. Stanley Mummery: A Case of Mandibular Sarcoma in an Infant.
Paper:
Mr. W. F. Broderick: The Endocrine Factor in the Production of Immunity or Susceptibility of the Teeth to Caries.
The following have promised to take part in the discussion after the paper:—Sir Arthur Keith, Dr. Leonard Williams, Sir John Bland-Sutton, and Prof. Halliburton.
Members of other Sections are invited to attend this meeting.

Thursday, Dec. 1st.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.
Specimens:
Mr. J. Ellison: (1) Squamous-celled Carcinoma of the Cervix Associated with Spheroidal-celled Carcinoma in the Body of the Uterus. (2) Unusual Case of Extra-uterine Pregnancy.
Paper:
Mr. R. H. Paramore: *Eclampsia and its Incidence.*

Friday, Dec. 2nd.

LARYNGOLOGY: at 4.45 P.M. (Cases at 4 P.M.)
Cases and Specimens will be shown by Mr. Mollison, Dr. Dawson, Dr. Douglas Guthrie, Mr. Howarth, Mr. E. D. D. Davies, Dr. Andrew Wylie, and others.

ANÆSTHETICS: at 8.30 P.M.
Informal Meeting: Tea, Talk, and Tobacco.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, Nov. 28th.—5 P.M., *Dr. Arthur Saunders:* Carcinoma of the Stomach.
TUESDAY.—5 P.M., Mr. Addison: Hernia (1).
WEDNESDAY.—5 P.M., Dr. Owen: Diagnosis and Treatment of Renal Diseases.
THURSDAY, Dec. 1st.—5 P.M., Dr. Grainger Stewart: Sciatica.
FRIDAY.—5 P.M., Mr. Addison: Hernia (2).
Daily:—10 A.M., Visit of Post-Graduates to Wards. 2 P.M., *In-patient, Out-patient Clinics and Operations.*

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
MONDAY, Nov. 28th.—4.30 P.M., Dr. J. Bright Bannister: The Hæmorrhages of Late Pregnancy and Labour.
TUESDAY.—3.30 P.M., *Dr. F. G. Crookshank:* Physical Examination of the Chest—The Stethoscope.
FRIDAY, Dec. 2nd.—4.30 P.M., Mr. E. Gillespie: The Treatment of Paralytic Deformities by Orthopædic Methods.
Daily:—2.30 P.M., In-patient, Out-patient Clinics, Operations, &c.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, Marylebone, W.
MONDAY, Nov. 28th.—5.30 P.M., Lecture:—Dr. R. O. Moon: Functional Diseases of the Heart.
Daily:—10 A.M. and 2 P.M., Out-patients and In-patients.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
THURSDAY, Dec. 1st.—6 P.M., Chesterfield Lecture:—Dr. W. Knowsley Sibley: Syphilis.

BRITISH ORTHOPÆDIC ASSOCIATION.
FRIDAY, Dec. 2nd.—Annual Meeting at the Liverpool Medical Institution (President, Sir Robert Jones). 10.30 A.M., Mr. H. A. T. Fairbank will open a discussion on The Late Results of Treatment of Congenital Dislocation of the Hip.—Mr. C. Thurstan Holland: Demonstration of Radiograms of Bone and Joint Affections. 2 P.M. (at the Royal Southern Hospital), Mr. T. R. W. Armour: Demonstration of Operations and Cases.
SATURDAY.—9.30 A.M., Mr. H. Platt: *Paper:* A Series of Endosteal Tumours. Mr. R. C. Elmslie: Demonstration of Endosteal Tumours and Bone Cysts. Mr. D. McCrae Aitken:—*Paper:* Function in Relation to Repair in Bone. 2 P.M., Visits to Hospitals.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURE at Whitworth-street West Branch, Manchester.
FRIDAY, Dec. 2nd.—4.30 P.M., Dr. Lacey: Backache.

HOSPITAL FOR SICK CHILDREN, Great *Ormond-street*, W.C.
THURSDAY, Dec. 1st.—4 P.M., *Lecture:—Dr. B. Shires:* X Ray Appearances of Diseases of Bone.

There were 3019 deaths from respiratory diseases, and 1515 from various forms of tuberculosis. Beri-beri was responsible for 555 deaths, as compared with 804 in 1918 and 651 in 1917. During the past few years circulars have been distributed to all large employers of coolie labour calling their attention to the fact that beri-beri is produced by the consumption of white rice as the staple article of diet without a sufficiency of other foods, and advising that beans should be supplied with the rice when fresh meat or fresh fish cannot be afforded.

Government hospitals consist of the Civil Hospital, to which is attached an isolated maternity hospital, the Victoria Hospital for Women and Children, and the Kennedy Town Infectious Diseases Hospital. There is an observation station capable of accommodating 1500 persons in the event of an outbreak of infectious disease on board a ship arriving in the harbour. In the Civil Hospital, which contains 166 beds in 20 wards, 3926 in-patients and 22,446 out-patients were treated during 1919; 218 cases of malarial fever were admitted; 460 confinements occurred during the year in the Maternity Hospital, which contains 12 beds for Europeans and four for Asiatics; 54 infectious cases were treated at the Kennedy Town Hospital. In the Lunatic Asylum 207 patients of all races were treated, and there were eight deaths. The Tung Wa Hospital, which is mainly supported by the voluntary subscriptions of Chinese, receives an annual grant from the Government. Only Chinese are treated in this institution, which performs other services as well as those appertaining to a hospital, such as the free burial of the poor, the repatriation of destitutes, and the organisation of charitable relief in emergencies. Chinese as well as European methods of treatment are employed in accordance with the wishes expressed by the patients or their friends. About half the number are now treated by Western methods. The hospital is managed by a committee of Chinese, who are annually elected. It is under the supervision of a visiting physician, who is a member of the medical department, whilst two Chinese house surgeons trained in Western medicine, are members of the hospital staff. There are 323 beds in the buildings, and 7002 patients were accommodated during 1919. The Tung Wa also maintains a branch hospital for small-pox cases (Chinese only). It contains 58 beds, and during 1919 four cases were treated.

The Alice Memorial and Affiliated Hospitals are managed and controlled by the missionaries resident in Hong-Kong, agents of the London Missionary Society. The number of in-patients in 1919 was 1305. To avoid the complete seclusion from friends and relatives which removal of Chinese plague patients to the Kennedy Town Infectious Hospital entailed, four District Plague Hospitals are maintained by the Chinese in various parts of the colony. The new Kwong Wa Hospital for Chinese in the Kowloon Peninsula was opened in 1911. There are 70 beds, and 3313 patients were accommodated during 1919.

The University of Hong-Kong is an institution that arose from the joint enterprise of British and Chinese subscribers. At the end of 1919 the number of students was 225, of whom 75 were taking the medicine course. The idea of the University is to provide, close to China, education similar to that given in the British universities, but at a much cheaper cost. The medical faculty offers ample facilities for the practice of medicine. The medical laboratories were the gifts of various Hong-Kong Chinese residents. There is a large staff of instructors in medicine, and all the principal medical practitioners in Hong-Kong give lectures at the University. Clinical work is carried on at the Government Civil and Tung Wa Hospitals. The degrees are recognised for registration in Great Britain by the General Medical Council. The University insists upon all students having a proper knowledge of their own language, although instruction at the University is carried out in English.

The mean temperature for the year 1919 was 72·2° F., as against 71·2° in 1918, and 71·8° for the past 36 years. The total rainfall for the year was 76·140 inches, as against 101·605 inches in 1918, and 83·020 inches for the past 36 years. The climate of Hong-Kong is similar in its broad features to that of Kowloon and the New Territories, but at the higher levels, from 1400 to 1800 feet above sea-level, the temperature is usually from 3° to 6° lower than at the Observatory, Kowloon. The humidity is usually greater than in Kowloon, and approaches saturation for several days at a time during March and April, when mist is very prevalent. In summer the City of Victoria and the rising terraces behind it derive little or no benefit from the south-west monsoon, being sheltered by steep hills from S.E. to S.W. In winter it is exposed to the north-east monsoon, which occasionally blows along the harbour, through Lyemun Pass, with considerable violence. On the other hand, the south-west side of the island is protected from the north-east monsoon in winter, and enjoys the benefit of the south-west monsoon in summer.

EXCESSIVE PRESCRIBING.

A practitioner was recently asked by his panel committee to justify two prescriptions each containing 6 oz. of Stokes's liniment (Lin. album). His chief concern was the unreasonable cost of this prescription, which was charged at 9*d.* for the liniment and 4*d.* for the dispensing fee. This pricing is in accordance with the official tariff and cannot, of course, be altered until this tariff is modified by the fall in the cost of drugs. The criticism of the panel committee was directed to the amount ordered on one prescription. It was considered that this quantity would be wasted, and that 2 oz., or at most 4 oz., was sufficient to order on one occasion. Only in exceptional cases would it be necessary to use more than 4 oz. of liniment in a week. The cost may appear a trifling matter in one or two cases, but considering the vast number of prescriptions given in one area the total amount may be a serious and unnecessary drain on the drug fund which is provided by the Treasury out of public money.

TO VENTILATE AND DEODORISE.

The "Win-Sum" radiator, recently patented by Messrs. Tidd, Siday and Co., Ltd., of 180, Drury-lane, London, W.C., is a combination of an electric radiator and ventilating fan. The radiator forms the front of a box in which the metal fan is placed. Air is drawn into the apparatus and forced through the four porcelain and wire "elements," each of which can be turned on by a switch, thus regulating the degree of heating of the air. The manufacturers claim that the consumption of two electrical units an hour by this apparatus produces a uniform temperature of 60° F. on cold days in a room 20 ft. by 20 ft. by 12 ft. 6 in. In summer the agitation of the indrawn air and its subsequent distribution throughout the room by the agency of the revolving fan produces a cooling effect. The box-like apparatus is placed on the floor of the room near the door; it is especially intended for use in ordinary rooms of houses but can also be employed to disperse the pockets of stagnant air not infrequently found in certain parts of the "auditorium" of kinemas and other places of public entertainment. Slabs of absorbent porcelain material, to be soaked in eucalyptus or other volatile antiseptic, are provided in order that various odours may be added to the air forced through the radiator. The cost of the radiator is £20 retail.

CENTRAL HEATING IN CHICAGO.

At the beginning of another winter and with coal at its present price it is of interest to note how the question of cold dwelling houses for the people is dealt with in foreign countries. A copy of the "Bulletin of the Chicago School of Sanitary Instruction," now before us, suggests at the first glance that in that city landlords in general are compelled by the sanitary authority to supply heat to their tenants, on the ground that otherwise a building is being maintained by them in a manner dangerous to health. It is to be gathered, however, from closer study of the article that at Chicago a large number of buildings divided into separate tenements are constructed in a manner which has been recommended here as desirable from the point of view of economy. Few, if any, such buildings, however, exist in the United Kingdom as far as we are aware. In Chicago the rooms in question have no source of heating, except that which is under the control of the landlord; although they are, or can be, supplied with gas apparatus sufficient for cooking. Chicago landlords, it is stated, are, as a rule, compellable by the terms of their leases to supply heating to their tenants, who can sue them for breach of contract. Where such covenants do not exist, or possibly where they do, the sanitary authority is prepared to act in the interest of the citizens. At present, as we have said, no such heating system is general in the United Kingdom, where most of the rooms let as living rooms are warmed by open fires or gas stoves. The flats, in London at all events, which are centrally heated, are lived in by tenants who are well able to enforce the terms of their leases. The experience of Chicago, however, may point to the desirability of considering the welfare of the tenant of working-class tenements, if and when any are constructed in such a way that the dwellers in them are dependent entirely upon the landlord for warmth in cold weather. It may, in other words, be desirable when any such buildings are erected to make it the duty of a public authority to see that they are sufficiently warmed to be safely inhabited. Tenants of the humbler class do not take leases with elaborate covenants, and often hold their rooms on such terms that they are not likely to bring their landlords into court.

C. B. W. has put his finger upon defaults that are common to every form of professional education. We are afraid that the medical profession would not welcome an examination in middle age to see whether a proper standard of knowledge was still being maintained.

Notes, Short Comments, and Answers to Correspondents.

KNOWLEDGE AND UNDERSTANDING.[1]

BY W. D. HALLIBURTON, M.D. LOND., F.R.S.,
PROFESSOR OF PHYSIOLOGY, KING'S COLLEGE, LONDON.

THE question, "What is Truth?" is likely to remain unanswered for many generations to come, if not for ever. Within the last year or two it has acquired new meaning in the discussions which have centred around the question of relativity so prominently brought before the scientific world by the researches of Einstein. I have not the special mathematical knowledge to pronounce judgment on Einstein's work; but so far as an outsider has been able to grasp its significance one may briefly say that it has been found that the old Newtonian laws regarding gravitation and the propagation of light have been found not immutable or even absolutely correct in detail, but are only relatively true at a given time in certain conditions of space. In the light of uncertainty regarding the fundamental laws of the physical universe, who can hope, in branches of science dealing with living things, to attain to perfect knowledge? The seekers after truth need not be discouraged, for they will often be rewarded with sufficient understanding to grasp some of its meaning and even to apply the latter to the good of mankind.

Astronomy and Chemistry.

The old laws of the physical world may not be flawless, but they have enabled astronomers to foretell eclipses with exactitude, to give us the Nautical Almanac with accurate information about the tides and numberless other data, to detect the existence and predict the appearance of new planets, and numerous other feats. In chemistry, the atomic theory is, I suppose, only relatively true. Certainly no one has ever seen an atom, still less the electrons which make up the atoms; nevertheless, such theories have played an overwhelmingly useful rôle in the progress of chemistry and physics; witness, for example, the prediction of the discovery of new elements, and the invention of new methods in the application of radiant energy for the alleviation of suffering.

Physiology and Medicine.

Coming now to the biological sciences, I shall feel more at home when I single out physiology for comment. The relationship of physiology to medicine is one on which I am never tired of dilating. I remember a time which succeeded that when anatomy and physiology were taught by the same professor, when physiology was regarded almost as an ornamental extra in most schools—being taught by a lecturer who was not a trained physiologist and had no idea of research—and when the physiological laboratory was all but non-existent. With the foundation of laboratories the professed physiologist came into being and by diligent work made discovery after discovery. But with a few brilliant exceptions the clinical observer and the laboratory worker seldom came together, and both physiology and medicine suffered in consequence. From this state of things we are now emerging; physicians are beginning to recognise that physiology is the corner-stone of medicine, and that medicine is or ought to be applied physiology. I look forward to a time when clinical teachers will, as a result of laboratory training and experience, have grasped the spirit of research and be able to teach medicine in this spirit of understanding. I do not say we have not such teachers now, but the future will, I am sure, give us many more.

Empiricism in Medicine.

Medicine is often wrongly reproached for its empiricism, but empiricism is the result of past experience. The reproach is only deserved when medical men elect that their studies shall remain empirical and do not discover causes and reasons. Take, as examples, some morsels of dietetic advice which are often heard from practitioners. (1) In a case of malnutrition take more fat, but preferably in the form of cream or cod-liver oil instead of olive oil or margarine, (2) in a case of high blood pressure abstain from the red meats, but take fish and poultry; (3) in a case of obesity take toast, but not bread, and reserve drink till the end of the meal.

The physiological explanation of the first piece of advice is now known, for the useful fats are those which contain the recently discovered essential accessory factor or vitamin. Time may show that the second and third are justifiable; some little thing, quantitatively small, but qualitatively all-important, may yet be found to constitute the difference between harmful and useful foods. When such a happy time arrives, when the doctor can give physiological reasons for the faith that is in him, shall we even then be nearer the absolute truth. We may have by then advanced a few steps, but that does not mean we should hesitate to push on. Increase of understanding at least will follow, and with it decrease of suffering and disease.

Enzymes.

We hear a great deal about the activity of enzymes or ferments. It is immaterial that a ferment may be an actual entity or a special phase of matter; ferment action is the great mechanism in the chemical and metabolic activity of the body. This fact is indisputable, although no physiologist has ever seen an enzyme in a state of purity, just as no chemist ever saw an atom, and recently acquired knowledge of the whole subject of immunology is in the same position. We talk glibly of antitoxins, agglutinins, precipitins, opsonins, anaphylactins, hæmolysins—names which are merely the result of a desire to crystallise theories in terms of speech. Such excursions of the imagination may not come into the domain of exact knowledge, but they have led to understanding of such an operation as vaccination—a purely empirical procedure in Edward Jenner's day—and have enabled practical men to devise corresponding means for the prevention or cure of other diseases.

Vitamins.

To turn to a subject already alluded to—namely, the vitamins. Hopkins compared them to the nails and cement in the building of a house; McCarrison compared them to the spark which makes the energy of the fuel effective in a motor-car. Such similes do not add to our knowledge, but they help our understanding; the vitamins are still unknown chemically, but has their study been useless? From the imperfect knowledge at present available immense benefit to mankind has already ensued in the matters of properly balanced diets and of the deficiency diseases in which absence of vitamins plays so important an ætiological rôle.

Permeability.

We owe to physiology many other conceptions beside those of enzymes and vitamins which have profoundly influenced all branches of medicine. Physical chemistry, for example, in physiological hands is one of these. A study of such questions as colloids, surface-tension, and permeability is not only of intense interest in itself but has done much of recent years to place the phenomena of life on an intelligible basis. From the wide field here opened up I will content myself with one example—namely, permeability, a subject to which my friend, Prof. H. J. Hamburger, of Groningen, has devoted a life of research. He began with red blood corpuscles, and then passed on to a study of secreting cells. The usual way of explaining the action of a secreting cell is to say that it has a selective action; on one side it is bathed with a nutrient fluid originating from the blood. At its opposite border it pours out a new fluid, we will say saliva. The statement that the cell selects from the lymph certain materials and rejects others implies that the cell has something akin to consciousness and choice, a vitalistic view which cannot commend itself to any lover of exact science. The passage of substances through cells and their membranes is regulated by various physical forces, such as filtration, diffusion, and osmosis, but these alone will not explain all the facts; the subterfuge introduced by the assumption of vital or selective activity is a mere confession of ignorance. Investigation of the permeability of the protoplasmic surface and its membrane has done much to enlighten that ignorance; the cell is permeable to some substances and not to others; it has no real choice as to what shall pass and what it prevents from passing. It has been proved further that different ions modify in various directions the normal permeability; hence the electric charge of the ions must be an important factor in determining the passage of substances through the cell and its plasmatic membrane. In diseased conditions the normal relationships in the ionic balance is upset and cellular activity becomes abnormal. Electric charge is one factor, molecular size is possibly another, solution affinities, surface-tension, &c., are others. Without attempting a description of all of these, suffice it to say that they are in the region of exact research and measurement.

Permeability of Cells to Sugar.

Such considerations may be amplified by a brief allusion of what is known in relation to the permeability of cells to sugar. The sugar of the blood is glucose (dextrose); it is always present in health, but is then entirely contained in the blood plasma; the corpuscles are impermeable to this variety of sugar except in that pathological state we call diabetes, where the normal permeability is deranged. That in linked neuronic systems of a given anatomical lesion must not be overlooked.

---

[1] Being the substance of an inaugural address delivered before the Midland Medical Society, Birmingham, on Nov. 2nd, 1921.

When, as remarked above, it is stated that the overwhelming bulk of evidence points to a general speech area in the left hemisphere, lesions in which are revealed clinically by varieties of aphasia, I do not ignore the exceptional cases, of which not a few have been put on record. Several valid explanations have been advanced in such cases: perhaps the *most significant is the possibility* of left-handedness occurring, if not in the individual concerned, then in other members of his family. There is something to be said for the "stock-brainedness" theory of Foster Kennedy. Crossed aphasia, so-called, may be due to individual peculiarities, for physiological as well as anatomical anomalies may occur. And, once again, there is the question whether in a particular case a microscopical examination of the cerebrum has been made.

PHYSIOLOGICAL.

To understand the physiological mechanisms employed in speaking we may clear the ground by a brief sketch of how speech is acquired. Long ere the child has begun to articulate, his ears have become accustomed to many and varied sounds, included in which are the sounds of words, mere noises to the child, without any meaning. Some of these sounds are repeated in his hearing much oftener than others, so that he gradually learns to distinguish them and to associate them with certain objects, animate or inanimate. We have no reason to doubt that, before articulate speech begins, the infant is using both hemispheres for vision and both for audition. The next step is the endeavour to imitate by articulation the sounds he hears constantly repeated by others, and in this way the movements necessary for the *articulation* of these sounds, or words, are learned. Again we must believe that both hemispheres are being utilised for speaking *movements*; before he learns to read or write, therefore, his "inner language" consists of the memories of certain sounds closely linked to the memories of certain movements, and the former of these is also intimately bound to the visual ideas of certain objects. When his nurse says "bow-wow" he will look for or point to his little toy dog, and when it is *shown him* he will say "bow-wow." Thus as early as he begins to think at all, he is developing his "inner language."

When the child reaches the stage of learning to read and write, his inner language becomes considerably more complex. He learns to write by letters and by syllables, which are the signs for sounds, be it noted, since our writing is phonetic. In this way he acquires a visual picture for each sound, made up of a letter or combination of letters, and so he reaches the stage of a visual knowledge of letters, syllables, and words. He learns to write, however, with one hand, and that the right hand. Hitherto, as we have seen, the presumption has been that both hemispheres have been utilised for hearing sounds, for articulating sounds, and for reading signs that stand for sounds. When he writes signs that stand for sounds, we must suppose he uses largely, if not entirely, a part of his left hemisphere only, as far as the physiological *mechanism* is concerned. Now if both hemispheres have thus shared in the acquisition of speech, how comes it that in the average individual it is only necessary to destroy a limited portion of the left cerebral cortex for a complete aphasia to result? The received explanation is the general right-handedness of the genus homo, but the inadequacy of this solution can be seen when it is realised that the difference between the daily work of the two arms is vastly less than the *corresponding* difference in function between the right and the left speech areas. According to Ernst Weber the final determination of the lead of the left hemisphere, from the viewpoint of speech, is that the child is taught to write with the right *hand*, and for this theory there is no little evidence. A physiological concentration of this sort, leading finally to *preponderance of the left* hemisphere in speech mechanisms, could not have occurred until writing with the right hand had become general among all classes. Arguing by analogy, one would suppose the musical functions to be more bilaterally and equally represented and certain researches (Mingazzini, Probst) go to substantiate the contention.

Still speaking physiologically, we are to bear in mind that a spoken word and a written word are movements, while on the sensory side a seen word is no more than a seen object, and a heard word than a heard noise. Before the child can write a single letter correctly he will scribble with his pencil and say it is "writing," and if to us it is an unintelligible scrawl it is identical physiologically with an intelligible scrawl. The infant's laryngeal noises may be unintelligible but they do not differ integrally from the laryngeal noises that we call words. All must, accordingly, come under the ordinary physiological rules for motion and sensation; and physiological disorders affecting both projection-systems, be they afferent or efferent, and physiological cortical centres for motion and sensation, may impair the reception or the execution of speech elements as of any other function elements.

Though it be a platitude that speech itself is something far beyond mere function of projection-systems, this sketch of the elements has been given because of the importance of recognising that on the physiological side the mechanisms relating to speech are in every way similar to those connected with the function of the non-speech parts of the brain. Impinging on motor and sensory projection-systems connected with the execution *or reception of speech components* is a complicated series of association-systems; they are "private paths" converging on a "final common" path, and lead directly or indirectly from cortical reception-fields to those concerned with motor innervation. Disorder of these transcortical association-systems underlies the clinical phenomena of aphasia *as ordinarily understood.* Stress is laid on the fact that, anatomically, association-paths between cortical projection-fields must start from, and run into, these fields; hence ordinary lesions of the latter must inevitably involve origins or terminations of such inter-central paths. For this and other reasons complete "isolation" of the physiological systems concerned must be practically an impossibility, though, on the other hand, there is no reason to doubt that limited *functional disturbance* of association-paths occurs, and that a relative separation of the speech area from non-speech areas is a *possibility. It* is important to bear in mind, further, that the same motor cells of the cortex, say those innervating mouth, lips, tongue, palate, are used at one time in the function of speech, at others in totally different physiological combinations, and, since the function of motor speech may be grossly disturbed while the cells can be utilised for other functions, we cannot suppose the physiological defect to be localised in the cell-groups concerned. It must be outside them. Theoretically, therefore, apart from clinical and pathological considerations, disorders of speech must be disorders, physiologically, of higher mechanisms which play on those of a lower physiological level.

PSYCHOLOGICAL.

The subject increases enormously in complexity and intricacy when we turn to read, heard, written or spoken words, not as sounds, movements, &c., but as symbols or expressions of ideas. Speech is symbolic thinking, as Head has again recently emphasised; to adopt an illustration of Lloyd Morgan's, used originally in another connexion, the anatomo-physiological basis of speech is as different from symbolic thinking as is the movement of the needle on the gramophone record from the tune it can be made to play. Nor, indeed, is our illustration complete, for some hold that abstract thinking may proceed without utilisation of any of the "images" of speech. Letters and words are the signs for sounds, as already mentioned, but words are, in addition, symbols of another order altogether; they have a "content," a "meaning": as Bastian said, they are the counters by means of

QUEENSLAND HOSPITALS FOR THE INSANE.

THE general report of the Inspector of Asylums for 1920 contains the following details of the mental hospitals and reception houses in the State. On Jan. 1st, 1920, there were 1738 males, 981 females, total 2719 persons certified as insane in the State. During the year 318 males and 180 females were admitted into the mental hospitals, of whom 265 males and 141 females were admitted for the first time, while 53 males and 39 females, or 18·47 per cent., were re-admissions, as compared with 18·57 per cent. during the previous year. From the mental hospitals 145 patients were discharged recovered, and from the reception houses 41. The recovery-rate was 49·16 males, 54·78 females, 51·99 total per cent. for all the mental hospitals and reception houses in the State. This result is extremely satisfactory, for a number of recoveries take place in the mental ward of the Brisbane General Hospital of mental cases that have not been certified, and therefore are not included in the above figures. In addition to those discharged recovered, 19 males and 9 females were discharged to the care of their friends and relatives relieved or not improved. During the year, 129 males and 65 females died in the mental hospitals and reception houses, the death-rate being 7·40 males, 6·69 females, total 7·15 per cent. of the average numbers resident.

The numbers remaining in all the mental hospitals and reception houses at the end of the year were 1746 males, 951 females, total 2697, in addition to whom 26 males and 40 females were out on leave of absence; so that there were 1772 males, 992 females, total 2764, on the books certified as insane in the State. These figures show an increase of 34 males, 10 females, total 44 on those of the previous year. The proportion of the insane in 1920 was 3·74 per 1000 of the population (males 4·61, females 2·79).

The lectures, demonstrations, and practice papers have been given to the nurses and attendants during the past year at all three mental hospitals in accordance with the regulations laid down by the State Nurses' Registration Board. The nursing staffs at the three mental hospitals at present are: Goodna, 132 attendants, 96 nurses; Toowoomba, 64 attendants, 85 nurses; Ipswich, 57 attendants, 48 nurses; making a nursing staff total of 482.

AN OUTLINE OF SCIENCE.

Messrs. George Newnes are bringing out in fortnightly parts an "Outline of Science," edited by Prof. J. Arthur Thomson, following on the lines of Mr. H. G. Wells's well-known outline of universal history. The general aim of the Outline is to help the reader to get a clear and concise view of the state of present-day science in order that he may be able to follow with intelligence the modern advances and to share appreciatively in man's continued conquest of his kingdom. To middle-aged and middle-aging people who keep in the running of domestic affairs and politics it will come as a surprise to see how the discoveries of men like J. J. Thomson, Ernest Rutherford, and Frederick Soddy have made archaic their childhood's conception of dead or inert matter. The electron theory is, indeed, only just beginning to show us what electric phenomena actually mean. Similarly, the discovery of hormones at the hands of men like Starling and Bayliss is changing the whole face of physiology. If Prof. Thomson succeeds in bringing home to a large circle of readers a lively knowledge of these things he will have performed a great service to his generation. Part I. contains the Romance of the Heavens and the beginning of the Story of Evolution. The illustrations are striking and on the whole well chosen, although the photographs of planets are curiously woolly, and it is difficult to think of a view-point in space to justify the pictorial representation of the solar system on p. 16. Such popularisation of science is in harmony with the effort of the Selborne Society, to which Mr. W. M. Webb, F.L.S., calls attention in a following letter.

THE SELBORNE SOCIETY AND CINEMATOGRAPHY.

To the Editor of THE LANCET.

SIR,—In a letter which I wrote during the summer I mentioned that the Selborne Society was interesting itself in cinematography. The time has evidently come when an endeavour should be made to take advantage once more of what we may call non-theatrical films. There are many matters in connexion with science generally and natural history in particular, with customs, history, and travel which interest a large proportion of the public. The Society is beginning by introducing films into its extension lectures, one of which, with the help of travelling motor lorries carrying projection apparatus, can now be given anywhere in the country. It is forming a cinematography committee with the object of introducing more films of the sort which we have described into the cinema halls, to arrange entertainments where theatrical films are in the minority, to build up a film library, and, when prices of apparatus and films allow, to introduce the cinematograph into the ordinary curriculum of schools.

Sir George Aston and Sir Gilbert Parker have signified their intention of joining the committee, which already includes the following: Lieut.-Colonel E. S. Amery, M.P., Sir W. Watson Cheyne, M.P., Capt. W. E. Elliott, M.P., Mr. Joseph Hood, M.P., Mr. R. B. Frere, Sir Sidney Low, Mr. Oswald Mosley, M.P., Mr. Leslie Scott, K.C., M.P., Sir Ernest Wild, K.C., M.P.

I hope that any of your readers who are able to help in any way will communicate with me.

I am, Sir, yours faithfully,
WILFRED MARK WEBB, F.L.S.
The Hermitage, Hanwell, W. 7, Nov. 19th, 1921.

AN ANCIENT SCOTTISH HAIR-CAST.

To the Editor of THE LANCET.

SIR,—Mr. Alfred Ela, of Boston, U.S.A., has written calling my attention to an omission from the bibliography of my article on Hair-Casts which appeared in THE LANCET of Oct. 15th. Mr. Ela's contribution was to the *Boston Medical and Surgical Journal* in March, 1918, and ran as follows:—

> ". . . Review in *Archeological Journal*, 1916, lxxii., 402, of Banff Charters, A.D. 1232–1703, viz., Oct. 9th, 1232, lands 'were granted to Master Neis, the King's Physician, by Alexander II.'; Neis 'is reported to have obtained this reward for the service of cutting a hair-ball from his royal master's heart.' While the service seems shadowy, the fee was substantial."

I am, Sir, yours faithfully,
Cardiff, Nov. 9th, 1921. IVOR J. DAVIES.

CYNOTHERAPY.

To the Editor of THE LANCET.

SIR,—In reply to Dr. W. J. Rutherford (THE LANCET, Nov. 12th, p. 1038) I enclose a recipe for dog oil copied from Pharmacopœia Londinensis, date 1659, by "Nich. Culpeper, Gent., Student in Physick and Astrology." The book contains the name of an old owner thereof, thus: "Peter Reid, Senor. His book. Trafalger."

I am, Sir, yours faithfully,
VERE G. WEBB, M.R.C.P.I.
Haverstock-hill, N.W., Nov. 16th, 1921.

Enclosure.

OLEUM CATELLORIUM 146, OR, OIL OF WHELPS.

Colledg.—Take of Sallet oyl four pound, two Puppy dogs newly whelped, Earth worms washed in white wine one pound; boyl the whelps till they fall in pieces, then put in the worms, a while after strain it, then with three ounces of Cypress, Turpentine, and one ounce of Spirit of Wine perfect the oyl according to art.

Culpeper.—It is excellent good to bath those Limbs and Muscles that have been weakened by wounds or bruises.

THE LATE COLONEL A. B. R. MYERS'S AUTOPHLEBOTOMY.

To the Editor of THE LANCET.

SIR,—In your obituary notice (August 13th) of the late Colonel Myers no mention is made of his authorship of "Life with the Hamran Arabs"—an interesting book describing a sporting trip in the Soudan in the year 1875. It contains an incident of particular medical interest—viz., the performance of autophlebotomy (pp. 282–3). Having been prostrated with intense headache and nausea for several days as a result of sunstroke, he thought that blood-letting would do him good. As he had no European companion present at the time to perform the operation he was obliged to do it himself. He first opened a vein in his left arm, but this was ineffectual; he then did the same in the right arm and was successful in causing a flow of 8 oz. of blood. This caused some immediate faintness but procured the desired relief. In bygone days, when venesection was practised frequently and was better understood than it is now, the performance of it by a medical man on his own *corpus vile* may have happened occasionally, but I think that it must be very uncommon. I cannot remember any case recorded in literature.

I am, Sir, yours faithfully,
F. LUCAS BENHAM, M.D., M.R.C.P.
Exeter, South Australia, Oct. 5th, 1921.

PUBLIC HEALTH IN HONG-KONG.

A REPORT for the year 1919, prepared by Mr. A. G. M. Fletcher, Colonial-Secretary, estimates the total civil population at 598,100, including 13,600 non-Chinese. The birth-rate for the year was 3·9 per 1000 among the Chinese community and 20·6 per 1000 among the non-Chinese, as compared with 3·6 and 22·1 in 1918. The death-rate was 23·3 per 1000 among the Chinese and 19·9 among the non-Chinese, as against 29·6 and 19·5 in the previous year. The number of deaths from malaria (310) showed a decrease. In the City of Victoria the deaths of Chinese from this cause numbered 101 out of a population of 320,080, or a rate of 0·3 per 1000 per annum. The deaths from plague numbered 426, as compared with 251 in 1918. Small-pox deaths numbered 15, all Chinese.

speech which may not be strictly necessary for comprehension but are, nevertheless, essential for correct speaking. It is more particularly prepositions and articles which are omitted and nothing really shows the poverty of the patient's language so much as their omission. The following letter was received from an aphasic in answer to a request for a report on his condition:—

> Dear Sir,—Speech, difficulty of speaking. Arm, leg, no improvement. Pain thumb, no grip. Loss of memory, serious. Brain fag recovering, although slowly.—Yours truly.

As the *child at school is taught to spell* by letters and by syllables, so acquiring his knowledge of the morphology of words, in a similar but reversed way the disintegration in the morphology of speech caused by a cerebral lesion may result in the aphasic's having great difficulty with letters and syllables, not as regards their enunciation but as regards their correct employment. He may lose his power of spelling, but apart from that he may persistently use wrong letters or syllables and *often a long trial-and-error* process is necessary to get the correct result. Thus one patient said "shapple," "shaplin," "shapnel" in succession before he got "shrapnel"; another said "tuning-thorn." "tuning-thork," en route to "tuning-fork"; and so on. Once more, the aphasic often begins sentences which he never finishes; sometimes he has two or three words correctly put together but ending "in the air." I asked one of my patients how he was, and the answer came: "Well, I can't . . . . I never . . . . I'm a little . . . It's really. . . ."

This defect is to be distinguished from what has been improperly called the "pseudo-agrammatism" of inability to recall the names of objects. In this case the patient will speak quite correctly but is forced to employ one periphrasis after another owing to his lack of substantives: and, on occasion, the emotional comes to the aid of the intellectual, as with a patient suffering from this amnesic difficulty who was shown a photograph of his son and asked what it was. He answered in a crescendo fashion: "*my* . . . . *it's* the . . . . it's my . . . . oh! . . . . he's my . . . . oh dear! . . . . he's my boy!"

This difficulty in naming objects, in finding substantives, has long been known and its definiteness led Mills, on clinico-pathological grounds, to postulate a "naming centre" in the temporal lobe; more recently, Head has coined the term "nominal aphasia" for a type which includes this particular defect. Undoubtedly disorders of the nature of agrammatism run like a thread through most of the clinical types, and yet we must take care to limit the conception. Pick emphasises the fact that higher grades of paraphasia and of jargon-aphasia, *for example*, ought not to be classed with agrammatism, since in them the impairment lies at another level; he furnishes evidence, nevertheless, that agrammatism and a degree of paraphasia are apt to occur in combination, and that their basis is disturbance of a physiological mechanism localised mainly in the temporal lobe. The subject needs further investigation. Recent work by Förster points to a frontal localisation for the mechanisms underlying the grammatical structure of speech; Maas, on the other hand, considers agrammatism the result of the imperfectly equipped right hemisphere essaying the function of speech when the speech areas of the left are destroyed by large lesions.

Some Considerations on the Clinical Varieties of Aphasia.

For that large class of case in which the patient is unable to understand what he sees or hears I prefer to substitute the term "receptive aphasia" for "sensory aphasia." As regards audition, it should be understood by the *student that* an aphasic may suffer either from word-sound-deafness or word-meaning-deafness, and that these two conditions are distinct. He may hear sounds and tones but not be aware that they are word-sounds; or he may know them to be word-sounds but have no idea of their meaning. A foreigner ignorant of English is word-meaning-deaf to the English tongue when he hears it spoken, but not word-sound-deaf. Similarly, as regards vision, the patient may be word-sight-blind, or word-meaning-blind. In the former case he sees written or printed letters, syllables, and words as mere objects, and is unaware that they are speech-symbols; in the latter he is conscious of their being symbols for ideas, but *these symbolic meanings are not aroused by the sight* of the words.

The subjects of *receptive aphasia* have usually considerable capacity for expression, but their words are often incorrect and their agrammatism is sometimes peculiarly pronounced.

A brief excerpt from the notes of a case of this description may here be given. Unable to read a word and incapable of appreciating any but the very simplest requests, the patient was asked "How are you this morning?" and in answer rambled on as follows: "Well, just the same . . . . I know all my six little boys . . . . right away . . . . I know them all myself like . . . . I do I know if I could get away like . . . . There's six of them plenty of them . . . . There's the thing and I can't . . . . I am myself then plenty . . . . I know myself then, poor little old dears . . . . There's three little old boys . . . . Six of this lot . . . . There's two of them like . . . . There's two little old boys . . . . I know it myself if I could have got it . . . . Little old boy . . . . Anna, Anna, Anna . . . . Three to-day, Anna . . . . Poor little old dears . . . ." &c., &c. In contrast to this largely meaningless logorrhea the same patient was able to express his meaning by rich and accurate pantomime and gesture, and while he failed to give a name to any object he indicated its use quite correctly. As for letters and words he was unable to name a single one. When given a little hand mirror and asked to name it, what he said was "That's two for Jimmie . . . . Anna . . . . Anna's the boy . . . ." while what he did was to *hold it up to his face and glance into it with a smile.*

With so difficult a line of approach to the examination of cases of *receptive aphasia*, it *is remarkable* that one is sometimes able to get an unexpectedly good response if one can "tap" acquisitions which have become automatisms. This is true, indeed, of most cases of aphasia. Some sufferers from the condition can sing what they cannot "say"; a patient sang accurately the air and the words of a ditty which begins "Oh, I'm longing for my dear old home again" when he failed to say or use any of the words in other combinations in speech. Another was unable to say any of the numerals to order, or to use any of them in a sentence, but when shown the figure 1 in *print* he suddenly began to count and counted rapidly to over 20, when he was told to stop. Henschen has recently collected evidence, worthy of the attention of the student, which suggests that such acquired *automatisms* are located physiologically in the right hemisphere; the problem in many cases of aphasia is not one of *destruction* of engrams but of inability to arouse them.

Word-deafness in the sense of *word-sound-deafness* sometimes occurs almost in a pure state. The sounds of words are not distinguished by the patient from any other sounds, but his auditory engrams are utilisable for reading, writing, and speaking, though he cannot repeat words on request and cannot write to dictation. Before making the diagnosis one must be sure that his actual hearing is unimpaired. Subcortical lesions in the temporal part of the speech area have been shown to produce this variety of aphasia.

Word-deafness in the sense of word-meaning-deafness is a condition of remarkable interest. The patient hears words and knows that they are words, but these word-sounds, reaching his auditory centres, do not from thence awaken the meaning of the word, the concept for which it stands. Such patients often repeat correctly, parrot-like, what they hear, not knowing what it means; they write correctly to dictation, or copy, or read aloud, without knowing the *meaning* of what they read or write. To this variety the name "transcortical sensory aphasia" has been given, a term which for reasons stated above is unsatisfactory.

An Introduction
TO
THE STUDY OF APHASIA.

A Lecture delivered at the National Hospital for the Paralysed and Epileptic, Queen-square, on Oct. 31st, 1921,

BY S. A. KINNIER WILSON, M.D. EDIN., F.R.C.P. LOND.,
PHYSICIAN FOR OUT-PATIENTS TO THE NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC.

APHASIA is a subject the study of which, difficult enough in itself, seems fated to be rendered more confusing and complex by controversy and by terminological disagreement. One of the factors in this intricacy is the possibility of approaching the problem from anatomical, physiological, and psychological sides alike, and investigators have not always been careful to avoid inappropriate transference of terms or even of conceptions from one system to another. For example, the term "centre" occurs with some constancy in descriptive accounts of aphasia, but its meaning has been so variable as often to lead to erroneous impressions. An anatomical "centre," an anatomical projection-area, may be exactly delimited, as in the case of the visual area in the calcarine cortex, the Betz-cell motor area of the precentral cortex, and so on. A physiological "centre,' on the other hand, indicates the focus of functional activity of the particular system concerned, and is not of necessity identical in site with its anatomical correlate; a "process" is not to be localised morphologically. Thus, for example, the physiological "centre" for motor cortical activity can scarcely correspond precisely to the Betz-cell anatomical system. Thirdly, however, cerebral function has a psychological aspect, and only too often has the writer on aphasia speculatively postulated psychical or ideational "centres" (e.g., Grasset's "centre O") which cannot possibly correspond to anything on the anatomical or physiological levels, but for which the same term is used. It will therefore be seen how unsatisfactory are the various schemata devised by the ingenious to simplify and organise the complexity of the cerebral speech mechanism. The plotting out of physiological centres on paper almost inevitably leads to the conviction in the student's mind that they stand for anatomical areas of the cortex, which is far from being the case, while the drawing of lines of communication between these physiological centres and a psychical or ideational "centre" makes confusion worse confounded.

Graphic anomalies apart, however, it is unwise in my opinion to divorce the psychical or psychological component from its anatomo-physiological counterpart. Speech is an intellectual process and behind the overt expression lies thought, but neglect of the anatomical and physiological basis of speech is largely responsible for the present confusion, for the psychologist is not interested in, or is tempted to ignore, the patiently acquired facts of cerebral localisation of function, and confines his attention to speech disorders as disorders of the psyche, the "localisation" of which is supposedly irrational. Yet when a small area of softening in the left hemisphere renders a patient mute, when another makes it impossible for him to read, the clinician must either forego all effort to correlate the two, or in spite of theories of psychical process must admit that local lesions of the brain may be associated with partial disorders of an intellectual mechanism. In this connexion not enough notice, I fear, has been taken of the work of Shaw Bolton in this country and of the Swiss school (von Monakow, Berze, Fankhauser) according to which there is evidence that certain layers of the cortex, considered in their whole extent, constitute the anatomo-physiological basis for certain forms of psychical activity, and, however long the step be towards proof, it is a step in the right direction.

A given aphasic symptom-complex may be looked at in three ways: What is the anatomical site of the lesion producing the defect? What are the physiological mechanisms involved? What is the nature of the psychological disorder? No study of the subject can make any pretence at completeness if any of these three aspects is ignored, nor, on the other hand, can it be harmonised with clinical data if anyone is elaborated at the expense of the others.

ANATOMICAL.

It seems superfluous to point out that by universal consent we are justified in stating that in right-handed persons the lesions apt to be associated clinically with disorders of the function of speech are situated in the left cerebral hemisphere, and in a certain part or parts of that hemisphere. According to Henschen some 1500 autopsies on cases of aphasia have now been made, and the cumulative effect of this weight of evidence, pointing as it does to the existence of a cortical speech area, cannot possibly be ignored. Exceptions but prove the rule. A glance at the charts published by Niessl von Mayendorf will suffice to show that lesions within a more or less well-defined cortical region, extending from the posterior part of the lower frontal lobe across by the island of Reil to the upper temporal and lower parietal areas, are likely to reveal themselves clinically by aphasia in one or other form. In the so-called negative cases mere macroscopical examination is insufficient. The histological study of the cortex has reached so fine a pitch that no case can be called "negative" if this has not been undertaken.

Whether localisation of lesions within this speech area, to correspond to clinical varieties, can be established is to some extent doubtful. The time-honoured division of aphasia into motor and sensory types—a physiological classification—recognises the existence of two differing groups whatever be the terminology adopted, and it is legitimate, physiologically, to distinguish efferent from afferent impairment of function. Whether it is useful may be another matter. As far as speech is concerned the doubt is whether one type of symptom ever occurs without the other, though it be in varying proportions. According to this "global" theory large lesions in the speech area are followed by gross aphasic disorders and small or limited lesions by limited aphasic disorder; in each case an aphasic disorder as a whole. The so-called pure cases of the condition—i.e., of one or other clinical variety to the exclusion of the symptoms of another—are in reality doubtful and their apparent occurrence is due, perhaps, to an unconscious trend towards schematisation; the more thoroughgoing the clinical examination the less likely are such cases to be recorded. It is a fact, none the less, to which attention must be directed, that in a given case disorder of speech may be largely limited to the receptive or to the expressive side, or indeed to but one aspect of reception or expression. There is justification, moreover, in seeking limited lesions for small aphasic disturbances, though no correspondence between anatomical size of lesion and physiological amount of impaired process is to be expected, in any regular way. The clinical symptom of astereognosis, or inability to recognise the qualities of an object by touch and so to name it, is the result, in cerebral cases, of limited lesions of the superior parietal lobule, a fact often demonstrated by operation or post mortem; and there is no good reason why inability to recognise objects by sight, or any other analogous defect on a similar plane, should not be equally the outcome of a lesion localisable with the same relative closeness.

The task of assigning disorder of function to site of anatomical defect is none the less peculiarly arduous. A tendency to correlate symptoms with naked-eye lesions and to ignore the necessity for the exact determination of their extent by the microscope is to be deprecated; further, the effect "at a distance" eclampsia supervenes. And if such lesions arise, a toxæmia must develop. A necrosis, a cloudy swelling, or even a mere persistent inactivity of cells of such important organs as the kidneys and liver, cannot exist to any extent without causing a toxæmia. If the liver is not working sufficiently, a rise of amino-compounds (and allied bodies) in the blood must occur §; and if simultaneously the kidneys are inactive, the percentage increase must become great. Such substances come largely from the intestine; and the importance of food, especially of protein food, in the rise of toxæmia is well known, and in the treatment of these cases relative or complete starvation holds a high place. Pinard, in many years' experience, had never seen eclampsia occur in a woman kept on milk for eight days (Smyly[16]). Hastings Tweedy allows water only; I agree with him that in these cases milk acts as a poison. But whilst Prof. Tweedy seems to think that milk or other foodstuff is absorbed unchanged or insufficiently changed, because of the absence of the proper enzymes or antibodies in the intestinal wall,[17] I am of the opinion that poisonous effects arise because the liver is incapable of playing its true part.

Toxæmia an Aberration of Normal Metabolism.

The toxæmia which ends in eclampsia is for me simply an aberration of normal metabolism, and eclampsia simply a uræmia, distinguishable from other acute uræmias only in the method of its production. The condition of the blood and urine in the pre-eclamptic state supports this view. It was recently pointed out that there is usually no increase in the non-protein nitrogen and urea in the blood in these cases, and that this fact serves to distinguish true *eclampsia from uræmia* due to chronic interstitial nephritis complicating pregnancy.[7] But how can such an opinion be admitted, if it is allowed that the liver is necrosed to any extent, or that its cells are rendered in any way inactive? We can understand that the urea should not be increased or should even fall, but it is impossible to think that *amino-compounds do not enter the blood* in greater extent than before, provided the intestine contain them. Indeed, a direct contradiction to the statement is afforded by the work of Killian and Sherwin, who found that in 22 cases grouped as hepatic toxæmias (in 20 of which convulsions occurred), the non-protein nitrogen was invariably high above the normal limit, being doubled in some cases. The uric acid, similarly, was much increased; on the other hand, the urea was diminished.[6] This is in line with the urinary changes. There is, I understand, in the urine of these cases a high proportion of undetermined nitrogen[18]; where can the latter come from, except from the blood?

Opinions of Other Workers.

Other workers have believed that the maternal visceral lesions are primary. Lever, in 1843, believed that puerperal convulsions result from undue pressure by the pregnant uterus on the renal veins; and that such changes as occur in the blood are due to the consequent interference with the function of the kidneys. In support of his opinion, he pointed to the differences which obtain in different pregnant women in respect of the bulging of the belly wall—arguing that such differences show that the kidneys must be subjected to more pressure in some than in others.* And although his conception fell through—because pressure on the renal veins could not be admitted, and because it did not explain the hepatic lesions, at that time unknown—yet subsequent authors have been unable to demonstrate that the differences in the belly wall, to which he referred, are without significance in this question.‖ Similarly, in France 50 years later, hepatic insufficiency is apparently regarded as explaining eclampsia. Bouffe de Saint-Blaise, following Pinard, apparently believes that a lesion of the liver is primary; and that such always precedes and indeed is the cause of the kidney lesions. But he admits that to explain the hepatic change is embarrassing. He attributes the lesion to "heredity, some previous disease, or some other morbid disposition"[2]—an explanation so weak that no one will accept it.

In recent years the difficulty has always been to explain the maternal visceral lesions; this difficulty has led to the postulation of a preceding toxæmia—arising from the placenta, the ovary, the thyroid, the breast, the intestine, and even from the fœtus itself. No one, apparently, has attempted to differentiate such a suppositious toxæmia from the toxæmia resulting when liver and kidneys have become diseased; yet clearly, if a preceding toxæmia arises, the two toxæmias must be very different. Admission of the existence of maternal visceral lesions before the onset of the fits does not, of course, dispose of the possibility that a strange toxæmia arises before the visceral lesions, or, indeed, that it causes them; but such an admission injures that hypothesis very severely, for granted the existence of such lesions, everything in eclampsia, except these lesions, is explained. Given the maternal kidney and liver lesions, it is unnecessary to look for a strange toxin arising from anywhere.

Rise of Maternal Liver and Kidney Lesions.

My conception is new in this, that irrespective of a preceding toxæmia, it explains the rise of the maternal kidney and liver lesions. In my opinion the necrosis is ischæmic—a necrosis due to a shutting-off of blood-supply determined by an occlusion, not of the supplying arterioles, but of the capillaries into which these arterioles lead; and the occlusion is produced, not by a thrombosis, but by a pressure. The thrombosis is secondary (not primary) to the necrosis; the pressure is an exaggerated intra-abdominal pressure, produced in certain cases of pregnancy, to which rises induced by activity, and especially by labour, are superadded. In some cases liver lesions, in others kidney lesions, may appear first and be most marked; as a rule, both arise together. Such a compression of the kidneys, for instance, will clearly explain the anuria, which in the presence of a toxæmia induces the fits. But a compression of kidneys and liver, if great enough and persistent enough, will explain the necrosis of their cells (and, indeed, of the preceding change), whereby a toxæmia appears. It will explain not only the visceral necrosis, but also the selectiveness of this necrosis; it explains necrosis occurring in the kidney and in the liver cells, whilst the cells of the stomach, intestine, and pancreas escape. That such a force is in play is indicated not only by the futility of alternative hypotheses, but by many positive considerations.

Outline of the New Conception.

With the time at my disposal it is impossible to do more than briefly outline this conception. It is based on the previous conception that intra-abdominal pressure is a vital force,[11] dependent on the reactions of the body wall muscles, and fundamentally related with general, and more particularly with visceral, metabolism. It was the natural result of the discovery that intra-abdominal pressure is raised in pregnancy, and of the reasoned opinion that this pressure is more raised in some cases than in others. It is confirmed by the incidence of eclampsia. Many considerations show that intra-abdominal pressure is intimately related with general metabolism,[12] and its increase in pregnancy has been demonstrated.[13] It was objected that the pressure found in accessible viscera is not an index of the intra-abdominal pressure, but the result of contraction of the gut wall.[15] But this view is untenable. In 1917 I performed Cæsarean section for eclampsia, and with the manometer in position made the following readings of which thought is carried on. Speech, in fact, is an intellectual process and it has always, therefore, appeared to me idle to attempt to distinguish speech disorders from intellectual disorders; the controversy, in any case, is bound to prove somewhat barren. Osnato has stated that intelligence in its widest sense, speech, and eupraxia, are one and the same process, and that they develop together and disintegrate together; if this is too much of a generalisation, it is nevertheless impossible, and impracticable if it were possible, to say where speech defect ends and general intellectual defect begins. Psychologically, speech disorders are disorders of the Gesamtpsyche; local lesions of structure, limited disorders of physiological mechanism, and partial disturbances of psychical process, cannot conceivably be superimposed one on the other within identical boundaries or be made to correspond precisely; the units of the standards whereby they are measured are not of the same order.

---

§ Caldwell and Lyle seem to think differently.

‖ Ahlfeld's conception (1908) seems to have been similar. He laid stress on the pressure within the abdomen, and pointed to the striæ in the skin as evidence of it. And he wrote:—"Without a preceding insufficiency of the kidneys, no puerperal eclampsia." But he believed that a specific poison is at work which only in pregnancy is secreted.[4]

But we shall make no advance in the study of aphasia as a cerebral symptom or a psychical disturbance if we do not take our stand on the clinical certainty that varieties of speech impairment occur, are recognisable, can be differentiated, and are of practical and localising significance. For the clinician the problems of aphasia have to be faced in exactly the same way as those of disorders of function of the non-speech parts of the brain.

CLINICAL FORMS OF APHASIA.

Much of the dissatisfaction expressed from time to time in reference to the classification of aphasic disorders is due to confusion of thought as to the basis of that classification. From what has already been said, it will be clear that aphasia can be classified in an anatomical, physiological, or psychological scheme, but we must avoid, as has been already remarked, any transference of the terms used in the description of defects of one of these systems to the defects of either of the others. Aphasia being, in essence, a symptom or symptom-complex, we might ascertain the general site of the lesions calculated to produce it, and endeavour to correlate clinical varieties with variation in the position of the latter. We might, conceivably, speak of frontal, parietal, temporal aphasia, &c., though such a scheme would be difficult to particularise. "Island aphasia" (Inselaphasie) is a term which has never come into vogue in this country, but it represents a form of aphasic defect which appears to be the expression of local lesions involving the island of Reil and in this sense is an anatomically descriptive term. Again, aphasic disorders are commonly classed as motor, sensory, or mixed; "transcortical motor" and "transcortical sensory" are further varieties capable of clinical differentiation; "conduction aphasia" (Leitungsaphasie), too, can be recognised. These are physiological distinctions, and though much is indefinite, and still more speculative, the physiological classification of aphasic disorder is in the first place thoroughly legitimate, and in the second place has proved of practical clinical value from the viewpoint of cerebral localisation.

A third classification takes into consideration solely the psychological side and analyses speech disorders as disorders of the Gesamtpsyche, anatomo-physiological correlates not entering into the scheme. The most recent and noteworthy endeavour to classify aphasia psychologically is that made by Dr. Henry Head, for the details of which the student may be referred to his recent papers on the subject. It may be questioned whether in the present state of knowledge a pure psychological grouping must not remain more of scientific than of clinical interest, but for that matter no one of the three schemes is by itself satisfactory. There are certain important psychological characteristics of aphasic disorder in a general sense, largely common to all varieties; on the other hand, there is a definite association between certain clinical varieties and the interruption of certain mechanisms of a physiological order. It appears to me that until further advance is made a psychological arrangement has the disadvantage of losing touch with cerebral function, while an anatomo-physiological arrangement is calculated to introduce an artificial simplicity into a particularly complex subject and to ignore what must always be its fundamentally significant side. Without prosecuting further this matter of classification I wish to direct attention to some points, consideration of which is an essential prelude to the study of the disorders of speech.

Intellectual and Emotional Speech.

To the acute intellect of Hughlings Jackson we owe appreciation of the difference between the "interjectional" and the "propositionising" use of words as symbols of thought. The former is an element in emotional and the latter in intellectual speech and one may be grossly affected without proportionate impairment of the other. In ordinary aphasia there is commonly relative conservation of emotional speech; it is not infrequently noted that a patient with a limited vocabulary, the result of disease, will nevertheless contrive to convey the most varied meaning to his words by alteration of inflection, tone, accent, stress, and emphasis, and this can be done even when he has but one word to say, but one string to play on. Often, too, abundance of gesture makes up what is wanting in intellectual speech. The aphasic may say "Yes" when he means "No" and may have to depend on emotional speech, or on one or other of the above makeshifts, to express his real meaning. Or, again, he can often ejaculate words emotionally which he cannot use at all in the form of a proposition—i.e., in correct, logical speech. One of my patients who suffered from motor aphasia in the ordinary sense saw a Zeppelin descend in flames one night on the outskirts of London and ejaculated "Hallelujah!" under the stress of his emotion, which word he has never since been able to repeat "propositionally." An aphasic patient may swear with fluency when no amount of urging will get the same words out in the form of a "proposition." In one case of paraphasia from a temporoparietal lesion the patient was so irritated by his frequent mistakes—at breakfast he said "pass the ink" instead of "pass the salt"—that an only too correct "damn!" escaped his lips, whereupon his wife rated him soundly for swearing before the children.

Loss of emotional speech, intellectual being preserved, has not been the subject of much investigation, interesting though it is. Years ago Brissaud spoke of patients who had lost "le chanson du langage," and who were incapable of adding emotional meaning to their words by the light and shade of accent and emphasis. Their speech was one long monotone. Elsewhere I have recorded a case of this description, but it is not clear whether such disorder may not accompany lesions at a lower physiological level than that of ordinary aphasia.

Agrammatism.

Not enough attention has been paid, perhaps, to the grammatical and syntactical aspect of the subject, which is of fundamental importance. As words are made up of letters and syllables, so sentences are made up of words, and they are intellectually meaningless unless they are properly constructed. The path from thought to intelligent expression lies through the sentence; hence in aphasia difficulties with the sentence are prone to occur, and the aphasic often reverts by a process of involution to the standard of the child learner, who has trouble with those parts of speech that are concerned with qualifying and correlating. In the words of Mills, the grammar of language no longer exists for the aphasic. Agrammatism as defined by Arnold Pick is "that form of pathologically altered speech in which the essential elements for the grammatical and syntactical structure of speech are either lost or imperfectly employed." Many clinical examples might readily be furnished. Arising out of the same basic impairment is the tendency of many subjects of aphasia to speak or to write in the "telegram style," omitting parts of

Incidence in Labour.

Lastly, there is the effect of labour to consider. Labour naturally causes, at intervals more or less prolonged, very great rises of intra-abdominal pressure; and if an exaggerated intra-abdominal pressure is related in a causal way with the rise of the maternal visceral lesions, labour should sometimes be related to eclampsia. Whilst eclampsia usually induces labour, the latter occasionally precedes the unconsciousness and the fits. Post-partum eclampsia, I submit, must be attributed to the effects of labour; in such cases labour no doubt acts on viscera prone to the disease, but this proneness is explained by the state of pregnancy—i.e., by the pressure which has prevailed. We know that the albuminuria of pregnancy is made worse by labour; and even that albumin, at times, first appears during this act—thereby bringing labour into line with the strains of athletes. Labour occasionally causes some transient change in the kidneys; so also it sometimes determines a change in the liver—even necrosis!

The evidence of accouchement forcé in eclampsia must be borne in mind. Before this treatment was superseded by Cæsarean section it was believed by some to have a pernicious effect—the reason, I submit, being that it caused too much straining. The inference is that too much straining acts deleteriously on kidneys already diseased, as also on a liver already inactive, about to necrose, or in parts necrotic. The effect of prolonged labour due to obstruction must also be remembered; from the evidence at hand it seems that even healthy kidneys and a healthy liver can become necrosed by this means. The history of vagino-fixation, should the patient become pregnant, appears to afford such evidence. Macan relates a series of disasters following the operation from the German School. Eclampsia occurred certainly twice, and I believe three times, being attributed to some angular distortion of the ureters due to dislocation of the bladder. But this dislocation of bladder and kinking of ureters will not cause necrosis of liver cells. The only factor at work to which this causation can be assigned was, I submit, the straining for hours.[††] [9]

Conclusion.

I shall not enter upon the question of the effect of an exaggerated intra-abdominal pressure on the blood flow through the viscera. I simply remind you that the blood in its course chooses the easiest path, and that not all organs, or all parts of the same organ, are supplied in quite the same way. The great mass of blood reaching the liver has first to pass through the gastric and intestinal capillary network—with the possibility of escape by œsophageal and hæmorrhoidal veins, or, indeed, with rupture of gastric capillaries, by way of the stomach, as black vomit—for instance, during labour—which I suppose every one has seen. And as regards the kidneys, the blood reaching the convoluted tubules has first to traverse the capillary networks forming the glomeruli, with the possibility of escape by way of the medulla. Clearly, if the blood is obstructed in the cortex but escapes by the medulla, the selectiveness of the necrosis in eclampsia is explained. Similarly, if the blood flow through the liver is sufficiently impaired, liver inanition and patchy necrosis becomes intelligible. The question is whether an obstruction due to pressure and sufficient to cause such changes actually occurs in these secondary capillary areas. Does a study of intra-abdominal pressure and of the incidence of eclampsia warrant the acceptance of the idea? I submit that the evidence more than suffices to justify such a conclusion.

[††] Ruhl made a journey of some hours to see a patient on whom he had performed this operation, on receiving from the midwife a message that though the woman had been in labour more than 48 hours, and the pains were very strong, the os uteri could not be felt (Macan). This patient, however, recovered without eclampsia.

VALUE AND COMPARISON OF RENAL EFFICIENCY TESTS.

By JOHN D. COMRIE, M.A., B.Sc., M.D. Edin., F.R.C.P. Edin.,

ASSISTANT PHYSICIAN, ROYAL INFIRMARY, EDINBURGH; LATE CONSULTING PHYSICIAN TO THE FORCES IN NORTH RUSSIA.

Various methods have been suggested during recent years for the estimation of the efficiency of the kidneys, both for the purpose of general prognosis and for guidance in treatment. It is necessary that any method to be generally employed should, in the first place, be both accurate in result and, in the second place, reasonably simple to perform. Among the tests discarded, at least to a considerable extent, as not fulfilling sufficiently these requisites, are the coefficient of Ambard, the test-meal or excretion-fixation method, and the diastase test. The coefficient of Ambard is a figure representing the relation between the amount of urea in the blood and the urea excreted daily in the urine. Objections have been raised against this method—by Chace and Myers,[1] that it does not give information beyond that obtainable by estimation of blood-urea; by Addis and Watanabe,[2] that the rate of urea-excretion is not dependent upon its concentration in the blood and urine; and by Van Slyke and Cullen,[3] that the method contains several inherent fallacies. The test-meal method of Mosenthal and Lewis,[4] which involves careful collection of the urine at two-hourly intervals throughout the day and rigid adherence to meal-times, is for this reason liable to fallacy; otherwise it is simple to carry out, and consists in the comparison of day and night urines in regard to quantity and specific gravity. The diastase test, which consists in estimating the activity of amylolytic ferment excreted in the urine, has been described by MacLean and Russell[5]; but as the amount of pancreatic diastase excreted both by healthy persons and by nephritics varies within wide limits, and as

Yet it must be repeated that however objectionable the nomenclature the clinical occurrence of the type must be accepted. Because of the persistent echolalia the patient is often taken to be demented; the most striking example of this variety of receptive aphasia I have seen was in an inmate of an asylum. For further information reference may be made to the recent admirable monograph on the subject by Kurt Goldstein. In severe atrophic lesions of the temporal lobe the syndrome is prone to occur.

For the familiar "motor aphasia" of the text-books I prefer to substitute the term "expressive aphasia." The patient cannot express himself in words, and this without paralysis of articulatory mechanisms, for what words he has he articulates correctly enough. He will show by his actions and his response to stimuli that his intelligence is largely unimpaired and that his sole handicap is inability to express what is obviously in his mind, except by such makeshifts as have already been mentioned. It is no uncommon experience to find the subject of expressive aphasia indicating by varied stress and intonation of his single word or few words how much meaning he is trying to put into them.

It is impossible to say where expressive aphasia begins or ends and nothing is to be gained by hard-and-fast delimitations which are, indeed, contrary to what one has reason to expect. In my use of the term I simply wish to emphasise the clinical fact that in the general class of aphasic disorders is a type characterised, above all, by this defect in audible expression of words. Allied to the above is a further interesting clinical variety whose chief feature is that the patient is not able to say spontaneously what he can easily repeat *to order*; similarly he cannot write spontaneously, or only very poorly indeed, whereas he copies and writes to dictation with fluency. Such cases bear a close resemblance to those cases of apraxia in which the patient is unable to perform spontaneously what he is able to do by imitating movements made in front of him. It would appear that what cannot well be said voluntarily, can be said on receipt of adequate stimuli from certain sense avenues. To this variety the name "transcortical motor aphasia" has been given, but we have seen that all aphasia is, physiologically, transcortical, so that the term is confusing and should be abandoned. Expressive aphasia in the sense of word-dumbness is undoubtedly apt to occur with lesions situated in the more anterior part of the general speech area of the left hemisphere, or with others that interrupt association paths from temporal and parietal areas converging on this anterior region.

RELATION OF APHASIA TO AGNOSIA AND APRAXIA.

Word-deafness and word-blindness are defects of recognition; the patient sees and hears but he does not understand. Now there are other defects of recognition than those concerned with words. He may see objects, but may not recognise them by sight; he may taste, smell, touch objects, but fail to recognise them by these sense avenues. He may fail by one avenue but succeed by another. The general name given to this symptom of failure to recognise is agnosia. Thus we may have visual, tactile, auditory, gustatory, olfactory agnosia. From this point of view word-deafness is a variety of auditory agnosia; it is agnosia for the sounds of words. "Transcortical sensory aphasia," as we have seen, is agnosia for the meanings of words. Exactly analogous defects can be demonstrated in the case of word-blindness and in the case of the musical functions.

On the expressive or executive side, the patient with expressive aphasia has no paralysis of the musculature of lips, tongue, palate, &c., but he cannot speak. In agraphia, there is no paralysis of the small muscles of the hand but he cannot write. The generic term now employed for inability to perform certain acts, where no paralysis prevents their execution, is apraxia. Looked at in this way, motor or expressive aphasia is apraxia of the lips, tongue, palate, &c., for the movements of speech. Agraphia is apraxia of the arm and hand for the movements of writing. Aphasia and agraphia may thus be, and not infrequently are, part of a larger apraxia—viz., apraxia for other movements than those implicated in speech. Sensory or receptive aphasia may be, and often is, part of a larger agnosia—i.e., an agnosia for other things than words.

CONCLUSION.

Appreciable advantages are secured by regarding aphasia as part of a wider cerebral syndrome—viz., that of apraxia and agnosia. If aphasia is to be considered a disorder of symbolic thinking, it is important to grasp the fact that such disorder may reveal itself where no words, as such, come into the question at all. Yet unless some explanation such as that provided by the conception of apraxia and agnosia is offered, the limits of aphasia proper will be stretched unjustifiably. A patient who dresses himself wrongly or makes mistakes or "short-circuits" in performing any act such as lighting his pipe, shows a disturbance which cannot by any legitimate means be regarded as aphasia, but the disorder is certainly one of agnosia or of apraxia. By the utilisation of these modern conceptions the way is paved for a more comprehensive insight into cerebral activities, both on the receptive and on the executive side.

ECLAMPSIA AND ITS INCIDENCE.*

BY R. H. PARAMORE, F.R.C.S. ENG.,
GYNÆCOLOGIST, HOSPITAL ST. CROSS, RUGBY.

IN presenting a new conception of eclampsia, I have in mind not the fits and coma, but the toxæmia and maternal visceral lesions. That the toxæmia causes fits and coma is admitted: the problem lies in the *causation of the toxæmia*. Several explanations have been suggested—notably that the toxæmia results from necrosis of the placenta; Young considers that it arises from a placenta undergoing autolytic changes.[20] [21] Presumably the placental toxins, besides causing a toxæmia, also determine the lesions pathognomonic of eclampsia. Whether Young would allow that the maternal visceral lesions are of importance with regard to the toxæmia he has not (as far as I am aware) definitely stated. In support of his opinion, Young referred, a year ago, to the effect of releasing a tourniquet above the shattered part of a limb.[21] It must be allowed that the absorption of chemical bodies (toxins) arising from the extravasated blood and damaged tissues does produce a toxæmia; but that absorption does not produce eclampsia. Such a procedure is not followed by convulsions and coma; nor has necrosis of the liver and kidneys been demonstrated *post mortem* in such cases.† How trying would it be if every bruise produced eclampsia! ‡ To suppose that changes of a like order in the placenta cause eclampsia is, in my opinion, equally absurd.

Rôle of Maternal Visceral Lesions.

My conception, as opposed to that of Young, is that the maternal visceral lesions explain the toxæmia. That such visceral lesions precede eclampsia must be admitted; they cannot be merely terminal events in the disease. Although we may believe that the hæmatomata of the liver, sometimes found, are caused by the fits, and even that the fits exaggerate the pathological process, the view that the fits cause the lesions is untenable. Sometimes there are no fits, and the case ends with coma; but coma cannot cause the visceral lesions. In the albuminuria, the presence of casts, vomiting, and manifestations of hepatic derangement we have evidence that a change in the kidneys and liver often occurs long before

---

*A paper presented at the Section of Obstetrics and Gynæcology of the Royal Society of Medicine on Dec. 1st, 1921.

† It is stated that the injection of the products of damaged muscle, experimentally, may kill the animal at once or later: and that in the latter case changes in the liver resembling those in eclampsia are found. (*Quoted by Young in his argument.*[21])

‡ According to Young, even a placenta, presenting no macroscopic change, may cause eclampsia.[21]

rectal pressure. In the left lateral position, into which the comatose patient was turned prior to operation, the pressure was 25 mm. Hg (in the normal non-pregnant the pressure in this position is 6 mm. Hg). In the supine position the pressure was 35 mm. Hg (in the normal non-pregnant it is 10 mm. Hg). On opening the abdomen (whereupon the incision simply gaped) the pressure dropped to about 30 mm. Hg; and after removal of the child the pressure registered was 10 mm. Hg. These measurements show that the pressure values found in pregnancy are not due to the tone or contraction of the visceral musculature, stimulated into activity by inserting the bag into some viscus. They indicate beyond doubt that the intra-abdominal pressure is raised, and raised considerably, above the non-pregnant normal.

Differences in the form of the abdomen, especially in development of its muscular walls, and in the degree of its distension, indicate that differences occur in intra-abdominal pressure at corresponding periods of pregnancy. It is reasonable to suppose that the pressure, as pregnancy advances, becomes greater in strong muscular women than in those who are weak. The former necessarily have strong muscular abdominal walls and strong muscular thoracic diaphragms, and when they become pregnant it is not difficult to understand that their muscles offer a more tenacious and marked resistance to expansion of the abdomen than do those of women more fragile or diseased (phthisical). It is to be expected that in primigravidæ, in whom the belly wall has never before been inordinately stretched, greater pressures should occur—other things being equal—than in pregnant multiparæ; similarly, it is obvious that tight lacing must cause greater pressures than in those who go loose.[5] So, also, the greater the abdominal distension per unit of time (as in twins, hydramnios, and concealed accidental hæmorrhage), the greater must be the pressure.

Incidence in Strong Pregnant Women.

It is just in cases in which such conditions obtain that the toxæmia of pregnancy is found and in which eclampsia is so prone to occur. I take them briefly in order. Many observers have stated that eclampsia selects, or appears more commonly in, strong muscular pregnant women. In spite of this recognition writers in recent years have paid little attention to the association, being apparently obsessed with the idea that some strange toxin arises as the primary event. Why do 60 to 80 per cent. of all cases of eclampsia occur in primigravidæ, especially in those of strongly muscular type? Are we to suppose that such are especially prone to develop strange toxins, from placenta or breast, intestine or thyroid, whilst the weak and diseased react otherwise? In the woman's first pregnancy, is her body, with its ancestral memories, unprepared for the state of pregnancy *because of good health?* If eclampsia depends on a lack of chemical adaptation, or on a proneness to develop strange toxins, then surely good health, robustness, and muscularity should not stand in such a conspicuous relation; moreover, eclampsia should occur as a rule quite early in pregnancy, instead of —as is usual—quite late. Another explanation must be sought for; it is to be found in the interference with visceral metabolism caused by the pressure change induced in pregnancy by the reaction of muscle. It is not surprising that if the intra-abdominal pressure is related to visceral metabolism, if its undue increase can cause metabolic aberrations, ¶ that such should show themselves more commonly in primigravidæ, and especially in strongly muscular primigravidæ. The proneness of such women to eclampsia is itself evidence that the preceding toxæmia is determined by a physical, not by a chemical disturbance.

Incidence in the Unmarried Pregnant Woman.

The case of the unmarried pregnant woman is important, for it affords experimental proof of this conception. How is her proneness to eclampsia to be explained? In such cases the placenta cannot be peculiarly liable to degeneration or necrosis; the manner of living must afford the explanation, and in this the fear of discovery plays the chief part. The only available means is constriction by corsets to prevent the abdominal distension which the woman in wedlock has no motive to hide. That these patients tight-lace is evident on inquiry.[14] This act, in my opinion, is the causal factor explaining eclampsia in these cases; and many writers have referred to the effect of dress on its incidence. There are other factors, of course—for instance, the patient's occupation. Many are domestics, who do house-work and washing; several also eat heartily, in spite of vomiting, wind, and indigestion. But these factors are subsidiary; they occur in many cases of eclampsia, but do not of themselves explain its prevalence in unmarried pregnant women.

Incidence in Other Types.

Primigravidæ, strong muscular pregnant women, and unmarried pregnant women, types so prone to eclampsia, may be regarded as forming a class by themselves. The selectiveness of eclampsia for these is sufficiently remarkable. But there are other types, which also form a group by themselves, the proneness of which to eclampsia is also remarkable. I refer to cases of multiple pregnancy, of hydramnios, of concealed accidental hæmorrhage, and of hydatidiform mole. The fact that eclampsia appears in such cases indicates that its cause does not reside in the contents of the uterus, because the contents in these several types are so different from each other. In spite, however, of their dissimilarity the uterine contents in at least three of these types—in cases of twins, hydramnios, and concealed accidental hæmorrhage — have one conspicuous feature in common—namely, that the size of the uterus for the period of pregnancy is more or less considerably larger than it should be. The condition obtaining in hydatidiform mole is for the moment uncertain, and I leave it for others to discuss.**

This increased size is a condition affecting intra-abdominal pressure; if the uterus grows more rapidly than is usual, then—other things being equal—higher pressures will prevail. The greater the distension of the abdomen per unit of time, the greater the response of the enclosing muscles. This response is not a nervous peculiarity or disorder: it is a normal, a natural effect. It is the result of the stretching of the muscle fibres, and of its degree and rate of progression. If the abdominal distension occurs at a greater rate than is usual in pregnancy, the spastic state of the enclosing muscles[13] must be induced earlier and have a greater effect. Even where the enclosing muscles are not well developed at the beginning of pregnancy, if twins or any of these other abnormal ovular conditions obtains, an exaggerated pressure may occur—especially if the increase in the volume of the uterus is acute (as in acute hydramnios) or sudden (as in concealed accidental hæmorrhage). In all these cases the more rapid advance of the abdominal distension has the same effect as originally good muscles; and if the latter in a first pregnancy determine an exaggerated intra-abdominal pressure, then a rapidly growing uterus in later pregnancies gives the same result. Thus, again, we have the relationship of an exaggerated intra-abdominal pressure with eclampsia.

¶ That ovarian cysts, by their mere pressure, can cause serious noxious effects, is plain from history. According to West (1858), among the causes which combine to destroy the patient is "the disorder of the functions of other viscera, as the tumour by its increasing size presses upon and disturbs them."[11] And Malcolm and Gibb (1921), referring to a case in which a very large quantity of fluid was removed from time to time from such a tumour, say: "The case now related shows that sometimes an ovarian tumour causes death simply from exhaustion and pressure . . . it was only by constantly removing the pressure that the patient could be kept alive."[16]

** Prof. Briggs has shown that the size of the uterus for the period of the pregnancy in cases of hydatidiform mole is often smaller than it should be.[9] The question is whether this is so when eclampsia—or, rather the preceding toxæmia—appears.

"TWILIGHT SLEEP"

AND THE GENERAL PRACTITIONER.

By CHARLES H. S. HORWITZ, M.R.C.S.,
L.R.C.P. LOND.,
RESIDENT PHYSICIAN, LONDON HOME OF TWILIGHT SLEEP,
STREATHAM, S.W.

THE administration of scopolamine-morphine as a routine during labour has now had an extended trial in this country, and it may not be inopportune to give details of my own experience of the treatment of a considerable number of cases by this method. The most erroneous ideas prevail even among medical practitioners as to its use and effects, and if this article serves no other purpose than to clear some of these misconceptions that undoubtedly exist, it will have been well justified. Many of my patients have had to run the gauntlet of repeated warnings and reprobations of well-meaning though misinformed friends, and women have told me that they dared not even tell their doctor of their intention to have twilight sleep, as he was an ardent opponent.

Current Misconceptions.

In a recent lecture delivered to the Edinburgh Branch of the Scottish Midwives' Association, Dr. Hugh S. Davidson said :—

> "Some doctors are wholly in favour of the use of twilight sleep in every case, and others are equally emphatic in condemning its use in any case. Some of the laity, especially those who have experienced it personally, swear by it, whilst others, credulously swallowing every tale they have heard, inveigh against it owing to its alleged effects on mother and child, repeating, with additions, the story they have heard that it has filled the asylums with idiots. I have been told such things by patients to whom I have advised its use, and I may say at once that I have never come across such cases, nor have I been able to discover any in the experience of my medical friends. My personal opinion is completely in favour of its use, as you can judge by the fact that I have used it among my nearest relatives."

I was amused by a question put to me by a local practitioner who had come to the home to see a patient privately. "Twilight sleep," he said, "may be all right for the mother, but what about the dead babies?" He was almost incredulous when I assured him that we had not lost a single baby in several hundred cases. Another practitioner of 25 years' standing told me that he had timorously employed scopolamine in a single case with what he described as alarming results for, after an initial injection of morphia gr. ¼ and hyoscine gr. 1/150, pains entirely ceased for a number of hours, much to his distress. He had never again had the temerity to try the method. He was much puzzled to know what procedure I should adopt in a case that might require internal manipulation, and was surprised to learn that chloroform is not contra-indicated in "twilight sleep." Misconceptions such as these are very common, and I could indicate many more; but sufficient, I think, has been said to show that the whole subject is much clouded and obscured by a fog of misunderstanding and prejudice.

Personal Results.

I now propose to give an unbiased statement of its use from my personal results. At the outset a little discrimination is needed as to when treatment should commence. If it be delayed too long the patient suffers needlessly; if it be administered too early it is more than likely the pains will cease for some time, as was the experience of my colleague detailed above. I make it a rule never to give the first injection until pains are coming regularly every ten minutes, or if these are not fraught with much discomfort, to wait until they occur at five-minute intervals in primiparæ. In multiparæ treatment should, as a rule, begin as soon as definite labour pains are first felt.

The patient has a preliminary enema and empties her bladder. The room is darkened and her ears stuffed with cotton-wool soaked in olive oil, so that her attention shall not be distracted by anything. The attendants wear soft slippers. The initial injection should consist of scopolamine gr. 1/150 and morphia gr. 1/6, given subcutaneously in the gluteal region. I know it is often usual to give morphia gr. ¼, but increased experience has led me to adopt the smaller dose, and I never repeat the morphia. In half an hour a further injection of scopolamine gr. 1/450 is given and usually repeated in half an hour. In big fat subjects the second injection often needs to be scopolamine gr. 1/200. Thirst is generally complained of early, and water should be given to relieve it, but when once amnesia is established water should not be mentioned. Subsequent injections, varying from scopolamine gr. 1/150 to gr. 1/450, are regulated by the memory test, which requires a little experience for its successful application. The patient is shown some familiar article—a watch, a comb, or a hair-brush—and asked what it is. If she is asleep wait until she is aroused by a pain. She will probably recognise the article. Half an hour later the question is put, "What did I show you a little while ago?" If she recalls it at once without any mental effort another injection is given at once; if she is hazy and has difficulty in recalling it to mind, another half an hour is allowed to elapse, when some other article is shown her. I usually exhibit my silver cigarette-case for the third test, and it is often described as something quite different—i.e., a piece of paper or an envelope—and it was once called a scalp. It is necessary to be sure that she thoroughly visualises it, as there is always some dilatation of the pupil due to the scopolamine. The article selected should be held a little distance away and in a good light, which is screened afterwards. Judged from her replies one gauges her mental condition as acute, clear, slightly clouded, or very clouded. Frequently, after a few injections, there will be no need for further testing, as the patient herself gives gratuitous evidence of satisfactory amnesia. When awakened by a pain she might give vent to some such expression as "Go down and get the bread and butter." "Leave me alone, John." "I have to go out to the shops now." She will fall asleep until aroused by the next pain, and then make similar remarks.

Effect on the First Stage of Labour.—When the initial dose is given at the correct time I am certain that the first stage of labour is markedly accelerated. I will go so far as to say that the time of the first stage is in some cases actually halved. I have given a good deal of thought as to why this should be so, and can only conclude that scopolamine in some way or another acts as an irritant to the uterine muscle—if not on all unstriped muscle. It certainly causes some diuresis, and as the drug is excreted by the kidneys this has the advantage of rapidly removing it from the system.

Effect on the Second Stage.—The second stage of labour is usually affected adversely, being often prolonged, and for this reason forceps deliveries are more frequent in "twilight sleep" than in cases without drug treatment. The irritant action of the drug plays no part in assisting the second stage, even when the drug is withheld until the second stage is reached. I was at first inclined to the theory that the hurrying on of the first stage might tire the uterus, causing a modified inertia, but I have since abandoned the idea, because, as just stated, the same delay occurs when the initial injection is given after full dilatation of the os uteri. I am now of opinion that the explanation lies more in the fact that the second stage is largely dependent upon voluntary assistance in bearing down for its completion, and voluntary effort is largely abolished in "twilight sleep." It is my invariable rule to allow the second stage to proceed for two hours, and then if there is no prospect of the immediate birth of the head I apply forceps with the strictest regard for asepsis. A few drops of chloroform are all that is needed to induce anæsthesia to the obstetrical degree. I have had no case of puerperal sepsis with the following technique :—

While I am "scrubbing up" a nurse thoroughly cleans the perineum with the aid of soap and water and a soft scrubbing brush. When the patient is ready, a Clover's crutch is applied, and she is placed across the bed on her back with the buttocks just projecting beyond the mattress, under which boards have been placed to make it firm. I wear a sterile gown and gloves. A sterile towel is placed over each leg, one across the abdomen and crutch, and one on the bed upon which the buttocks partially rest. I swab the vulva well with lysol, ʒi. to the pint, and also the vagina, the test is troublesome to perform, it has not found general acceptance.

Tests for Estimation of Power of Kidneys.

The three tests which, in the writer's opinion, are of most value in helping the clinical observer to form an opinion as to the power of the kidneys are: (1) the phenolsulphonephthalein test; (2) the urinary urea-concentration test; (3) the amount of blood-urea. Cases illustrating the figures afforded by these tests and the results deduced from them are included in the following three tables. In the first place a brief outline of the methods will be given.

1. *Phenolsulphonephthalein Test.*—This test, introduced by Rowntree and Geraghty, has been used by the writer for the past nine years, both in civil practice and in the army, with uniformly satisfactory results as regards prognosis in kidney cases. It is carried out by injecting 1 c.cm. of fluid containing 0·6 g. of the pigment into the muscles of the back or limb. At the same time the patient drinks 600 c.cm. (a tumblerful) of water, and empties his bladder. This urine is discarded. Thereafter at one hour and two hours precisely the patient again passes all the urine in his bladder and these two samples are tested for the amount of pigment contained in each. For this purpose the one-hour sample is rendered alkaline by 10 c.cm. of 10 per cent. sodium hydrate solution, diluted to 1000 c.cm. with water, and filtered to remove any phosphates precipitated by the alkali. A portion is placed in one container of a Duboscq colorimeter for comparison with a portion of a solution consisting of 1 c.cm. of the testing fluid similarly diluted to 1000 c.cm. and placed in the other container. The tints being matched by turning the screws of the containers up and down, the percentage of pigment excreted in the one-hour sample of urine is calculated as follows: $\frac{N \times 100}{U}$ = percentage of pigment excreted, where N is the height of the column of fluid in the container holding the standard dilution and U the height of the column of diluted urine. For example: if N stands at 20 mm. and U at 40 mm., then $N \times 100 \div 40 = 50$ per cent. of the pigment excreted at the end of one hour. The second-hour sample is treated in the same way, and should contain considerably less pigment than the first-hour sample. If the same amount or more pigment is excreted in the second hour, this indicates delay and a depressed renal efficiency. The amount excreted in the two hours added together should total at least 70 per cent. in health, and may rise to 85 per cent. or even 90 per cent.

Other forms of colorimeter, such as that of Hellige, where a permanent standard is employed for comparison, are less satisfactory than the Duboscq, because their readings may be vitiated to the extent of 10 per cent. or more by the fact (personally observed by the writer) that the contents of the phenolsulphonephthalein ampoule supplied by different makers vary considerably both in quality and in depth of red colour. This difference does not affect the reading of the Duboscq colorimeter, in which the standard used is the contents of an ampoule similar to that from which the patient receives the injection. Great care must be taken in carrying out this test that the patient receives exactly 1 c.cm. of the fluid, that the bladder is completely emptied at the end of each hourly period, and that the injection is not made into œdematous tissue, from which absorption takes place slowly. It should be remembered that this test is really a criterion, not merely of kidney activity, but also of the whole mechanism of absorption, circulation, and excretion of the pigment. For this reason the writer prefers the muscles of the arm for injection rather than those of the back, where œdema is apt to collect, especially in bed-patients with kidney or heart disease. An important fallacy may be introduced by the presence of blood in the urine. To eliminate this in cases of acute nephritis, the urine should be allowed to sedimentise for 12 hours and decanted, or it may be centrifuged. In this way an approximately accurate reading can be obtained; otherwise, in acute nephritis the result of this test may be much more favourable than the actual excretion of pigment warrants.

2. *Urea-Concentration Test.*—This test, introduced by MacLean and de Wesselow,[6] is very simply carried out. It depends on the fact that if 15 g. of urea be administered by the mouth to a healthy person, it is quickly absorbed and excreted in the urine. In a specimen of urine passed two hours after the ingestion of this amount, there should be at least 2·5 per cent. of urea, while usually in a normal person the amount is 3·5 or 4 per cent. or in occasional cases more. If the proportion is only 2 per cent. or less it indicates a lessened power on the part of the kidney to concentrate urea, moderately severe cases of nephritis excreting only 1·5 per cent. or thereabout; while in severe cases, when uræmia is present, it may fall below 1 per cent. The test is carried out by administering orally 15 g. of urea dissolved in water. (This amount, which is equivalent to the daily excretion on a low protein diet, does the patient no harm, and is not unpleasant to swallow. The writer's practice is to carry out the phenolsulphonephthalein and urea tests concurrently, the urea being dissolved in the 600 c.cm. of water, which the patient drinks for the former test.) One hour after the urea has been administered the bladder is emptied and the specimen measured. At the end of the second hour, when the urea excretion is at its height, the bladder is again emptied, this specimen is measured, and the urea contained in it is estimated by the ordinary hypobromite process. Gerrard's apparatus may be used for this purpose, in which case 8 c.cm. of nitrogen is the equivalent of 0·5 per cent. of urea. If the urea-tube of Doremus be employed, two of these tubes must be used in each estimation, since the reading on the lower part of the scale gives too low a result in urines which contain an approximately normal amount (3·5 – 4 per cent.) of urea; the 1 c.cm. of urine, measured by the special pipette, is divided between the two Doremus tubes containing hyperbromite solution, and the readings of the nitrogen that collects in the two are added together. The estimation of urea-concentration and the phenolsulphonephthalein excretion do not always show absolute parallelism, but, generally speaking, they fluctuate together and in cases where they disagree the two methods form a useful check upon one another. If they differ to any considerable extent the tests should be carried out again next day.

3. *Blood-Urea Estimation.*—The amount of urea in the blood can be estimated without elaborate apparatus by means of the Soya bean "urease" ferment. The method as described by MacLean and Russell[7] is carried out by taking a small quantity of blood (3 c.cm.). This is incubated in a water-bath at about 40° C. for 15 minutes along with a small quantity of finely-powdered soya bean, the urea being thus converted into carbonate of ammonia. The ammonia is subsequently drawn over by the action of a water-suction pump into 25 c.cm. of centi-normal sulphuric acid, which after half an hour is titrated against 25 c.cm. of centi-normal sodium hydrate. The difference found by titration corresponds to the amount of sulphuric acid already neutralised by the ammonia evolved from the urea in the blood. From this the amount of urea is simply calculated, every cubic centimetre of difference being equivalent to 10 mg. of urea per 100 c.cm. of blood.

A few points demanding caution may be mentioned. The soya bean powder should be as fine as possible and if kept too long may be found inert, but it retains its fermenting power for at least several months after being ground. The temperature of the water-bath should not be allowed to rise above 45° C., as the ferment is apt to be destroyed above that temperature. The blood must be examined within a few hours of being drawn, because under certain conditions ammonia-producing bodies quickly form the superiority of their plaster work and especially of their splints, made of celluloid from a cast of the affected part, fitting perfectly, and therefore preventing reactivation and relapse; recidivism we know to be a pitfall in every form of tubercle. The point I wish to put is that a great deal of this work can be done, in his own district, by each tuberculosis officer.

Hygienic conditions in a working-class home are admittedly far below those of a country hospital; but then the home task is much easier. Consider the severity of the cases at Alton—bilateral morbus coxæ (I have seen only one such around Barnsley in seven years), cases with other multiple lesions, facial and skull caries (I had never seen this before), paraplegic patients, lardaceous disease, and so on. This allocation of patients is, to my mind, just as should be. The extra facilities and skill are best bestowed upon the unfavourable case. Early and slight disease may quite well be treated at home. In bone and joint tubercle the main principle of disposal is surely the converse of that in lung tubercle. Incipient consumption is sent to the sanatorium, while highly active or extensive affections are excluded therefrom; but, speaking generally, and with one or two exceptions to be mentioned below, in osseo-articular lesions, the early case should be kept at home, the more advanced sent away.

Description of Cases.

The above theses it is hoped to defend with a short account of the 30 patients with bone or joint disease treated here, as stated, in the last two years. They are as follows: Hip alone, 9; hip and knee, 1; spine, 8; knee alone, 7; elbow, ankle, 2 each; wrist, 1; total, 30. Of the 30, 22 were new cases coming under notice within this two-year period; these new cases comprised 1 elbow, 1 hip and knee, 4 knees, 7 spines, and 9 hips. Fewer than a third of the 22—viz., 3 hips, 2 spines, and 1 knee—needed sending away for institutional care. Two of these three hips were in very young children, in whom, as is taught and as I have found, recovery is slow; for early infection of itself argues a relatively unfavourable outlook; besides, sick infants require more attention than can be expected from an overtaxed working-class mother. The girl with an affected knee was sent off, after responding well to treatment, in deference to the teaching that tuberculous arthritis in that situation is on the whole of peculiarly unfavourable prognosis. However, from subsequent experience with patients who for indifferent reasons had to stop at home, I regret I did not keep the case and save the institutional bed for a worse case; more especially as the girl has just been discharged from Alton with arrested disease after the unusually short stay of three months. Both the spinal patients came from bad homes, one being an adopted child and the other of very poor parents. Thus medical considerations alone did not by any means dictate the choice in every instance.

The remaining 16 domiciliary patients all did, or are doing, practically as well as I have seen cases do at Alton and at Rivelin Valley, the Sheffield surgical tuberculosis hospital. Our plan of home treatment—and, be it noted, whatever the destination of the patient there is some unavoidable delay during which he or she remains at home and may as well be started on the road to recovery—our plan is to have the child's bed put next an open window, preferably on the ground floor for convenience of the mother. Then appropriate extension is applied, hyper-extension by means of a pad under the mattress in spinal disease, extension by weight and pulley for morbus coxæ. In one knee case with considerable flexion of the joint and subluxation of the tibia, straightening was effected by the "triple extension" apparatus, with its application of the parallelogram of forces, in five weeks; after ten had been spent fruitlessly in a general hospital with simple horizontal traction. It is soon seen if muscular spasm is disappearing at something like the normal rate. In hip disease, adduction or abduction will take long to correct, but if flexion does not yield soon, the bed-foot pulley having to be lowered something like three inches a week, then the case is obstinate and had better go to a more favourable environment. Simultaneously cold abscesses can be aspirated. When quiescence of the lesion is obtained with good position, then a plaster can be applied and the patient allowed up, of course on crutches in leg cases. Finally—often immediately—a plaster cast of the part is taken and a celluloid splint made. By the time this is worn out or outgrown, progress has usually been sufficient to render its replacement unnecessary. However, some further time should usually elapse before resumption of school attendance, because that depresses the general health and means extra risk of trauma. This interruption to education, avoided at special institutions by having visiting teachers, is the only absolute disadvantage of domiciliary treatment. But certainly there are not enough special institutions to treat all bone and joint tuberculosis, nor, as things are, enough funds available to increase their numbers or beds sufficiently. Besides, for adult patients the available accommodation is even more exiguous.

Results.

Of the 30 cases, 6, as stated above, were despatched to institutions. Quiescence of the lesion was secured in 14 of the remaining 24. By quiescence I mean disappearance of pain and muscular spasm, healing of any sinus or cold abscess, improvement in the general health, and complete or considerable correction of deformity. Three of these, one an ankle and one a knee, both with unmistakable clinical evidence of disease, the third a hip in which the diagnosis was confirmed radiologically, have now for some time discarded all apparatus and enjoyed full return of function. In four further cases the lesion was quiescent when the patient first came to my notice. This leaves 24 less 18, or 6 patients whose disease remains active. They are all adults, two of them ex-soldiers. An elbow (in plaster), a dorsal spine (in bed), and a knee (in a celluloid splint; operation refused) are slowly improving. Another spinal case is stationary. Two, a hip with many sinuses, and a knee far advanced in disease and complicated with extensive phthisis when first seen, are getting worse. There have been no deaths.

Of celluloid splints we have made 19 and repaired 4. Besides their remedial effect, they have sometimes given—as in the cases last cited—much palliation, and have rendered patients less of a drag upon their friends. Patients naturally prefer them to leather and iron appliances. Nurses take well to the preliminary stage of their construction—the pasting of layers of book muslin on to the plaster cast with celluloid dissolved in acetone—as it much resembles dressmaking. The later stages, fitting, riveting on of leather and duralumin, one must do all oneself. Its technique, like that of lung collapse, of nose and throat work, and of the rest of our speciality, needs proper learning, but, as the event has shown, is within the compass of a mechanical faculty distinctly subnormal. The admirable polish bestowed at surgical tuberculosis hospitals is not essential; and this saves time. That time which is indispensable is well spent: it looks as though in a year or two one could be master of the osseo-articular tubercle in one's district.

My thanks are due to Sir Henry Gauvain, to Dr. C. L. Pattison, surgical tuberculosis officer of Sheffield, and to their respective staffs—among whom must be named Mr. Green, orthopædic carpenter at Alton, whose hollowed leaden stand is most useful in the shaping of duralumin supports; and, lastly, to my two nurses for their keenness and industry.

HONOUR TO A SOUTH AFRICAN MEDICAL MAN.—On Oct. 21st, a presentation, consisting of a handsome silver tea and coffee service and salver, was made to Dr. M. W. W. Cowan, of O'okiep, Namaqualand, South Africa, on the occasion of his silver wedding, on behalf of the people of Namaqualand. Dr. Cowan has practised in the district for over 20 years.

and too high an estimation results. The blood must be withdrawn before the administration of urea for the concentration test, since a considerable rise in blood-urea follows within two hours after the ingestion of the 15 g. of urea. The test is extremely delicate and reliable, however, and repeated examinations give practically identical results. The normal blood-urea lies between 20 and 40 mg. per 100 c.cm. Any estimation showing over 50 mg. may be taken as indicating urea-retention and a decided degree of kidney inefficiency. When it is over 100 mg. the patient is usually a chronic invalid, the highest figures (e.g., Cases 2, 9, and 13 of Table I.) being obtained in cases of chronic parenchymatous Bright's disease. A blood-urea reading of over 200 mg. may be taken as an indication of impending death, though it may rise (e.g., Case 12, Table I.) to 371 mg. or higher; in another case (puerperal septicæmia, showing fatty degeneration of the kidneys on post-mortem examination) it rose to 268 mg. just before death. As a rule the blood-urea changes slowly. In subacute Bright's disease it is not greatly raised, but in the uræmia of acute nephritis and in febrile diseases like pneumonia it may be raised temporarily considerably above the normal level. The negative evidence that it affords, in combination with other tests, is of great value. For example, one case with severe headaches and albuminuria, supposed at first to be nephritic, was found to have blood-urea 22 mg., phenolphthalein excretion 86 per cent., and urea-concentration in urine 6 per cent.; the kidneys were therefore exonerated and the case was subsequently found to be one of enteric fever. Another case of headaches with albuminuria had blood-urea 31 mg., phenolphthalein excretion 90 per cent., and urea-concentration in urine 3·7 per cent.; the albuminuria speedily disappeared, the case being one of neurasthenia with periodic albuminuria. In still another case of headaches, ultimately found to be occupational in origin, the blood-urea was found to be 21 mg., phenolphthalein excretion 90 per cent., and urea concentration in urine 2·5 per cent. In cases where the kidney disease is moderate in degree, the blood-urea may be constantly well within the normal limits, and the prognostic indications must then be drawn from the other tests.

above 50 per cent. return to a moderate degree of health ensued; the urea-concentration always tended to be low, as the kidneys were readily stimulated to secretion of water, but in favourable cases the urea rose to about 2·5 per cent. before the patient left hospital. In cases of this type both blood pressure and blood-urea tend to be exceptionally high, but there is no relationship between the two, because when the blood pressure falls, as it readily does under treatment, no appreciable change takes place in the blood-urea.

Commentary on Table III.—This table includes cases in which the primary defect was cardiac, but clinical evidence of secondary renal involvement was present. In these the blood-urea is normal or only slightly raised. Whilst auricular fibrillation is present, the phenolphthalein excretion is considerably lowered, it may be to 20 per cent.; and the urea-concentration is low. Both characters of the renal secretion tend to improve as the heart recovers power. It is probable that some of the debility and danger in these cases of auricular fibrillation is due to the renal inefficiency. The complete recovery of health in Case 26 and the ability of Case 24 to maintain his life despite several very severe cardiac lesions were associated with an almost normal state of renal efficiency as revealed by these tests. The important feature has been frequently noticed by the writer that if, in cardiac cases, the kidney efficiency tests give an approximately normal or only slightly lowered result during the period of cardiac decompensation a very favourable prognosis can safely be given.

Conclusions.

1. The combination of the estimation of blood-urea, of urea-concentration in the urine, and of phenolsulphonephthalein excretion, gives reliable information as to the functional efficiency of the kidneys.

2. The blood-urea estimation should form a preliminary investigation. If it rises above 50 mg. per 100 c.cm. of blood the condition is serious. If it is found to be persistently over 100 mg. recovery is not likely, and death will probably take place within a year. In uræmia it may exceed 200 or 300 mg. before death. The blood-urea may be normal while a marked degree of renal impairment exists; but in such cases the immediate prognosis is usually favourable.

3. The blood pressure shows no constant relation to the amount of blood-urea; though when blood-urea is permanently high the blood pressure is usually h

articles contributed recently to that review gave his full adhesion to Guelpa's views. This testimony is the more valuable as he was once an opponent of Guelpa. Dr. Laumonier observes—and therein I agree with him—that on the first day there may be some slight discomfort, but that on the second day of purgation and fasting all discomfort disappears, to give place to a marked feeling of well-being. Dr. Laumonier is very insistent that absolute abstinence from all solid or liquid food should be observed during the period of the fast, and this is my experience, excepting for weak cocoa, which Dr. Guelpa recommended. The treatment is drastic and should always be taken under medical direction, but according to the testimony of these French authorities no accidents have occurred in the use of this remedy.

Method of Resumption of Ordinary Diet.

At the termination of the first long fast it is important to commence with a very restricted diet—e.g., one litre of milk, or 200 g. or 300 g. of green vegetables cut up or served in soup, or 200 g. of potatoes in soup. At the end of two or three days these rations may be increased by the addition of biscuits or toasted bread, milk dishes, and one or two eggs. After eight or ten days of this light diet a return may be made to ordinary meat diet. Analysis in the case of diabetics will show whether it is necessary to revert to the fasting remedy, but in many cases a complete cure has been effected with one course of the treatment. The French school recommend that the patient will be well advised to repeat the long fast from time to time—say three or four times a year in the hot weather.

Treatment of Acidosis.

I am confident that the adoption of Guelpa's method of combining rather free purgation with fasting will prove of great benefit to patients suffering from diabetes, gout, colitis, and arthritis if the treatment be applied under medical care and direction. The imporance of constant watching on the part of the medical attendant arises from the possibility of the development or increase of acidosis during the fast, as in my own case this year. In that event the fast should be discontinued when the acidosis is detected, and resumed after a few days. In the meantime, in my own case a single dose of codein sulph. ½ gr. and urotropin 5 gr. and the reversion to food immediately stopped these symptoms. After a week of light diet the fasting can be resumed with a diminishing tendency to acidosis. I think Dr. Guelpa would have depended entirely upon a temporary return to food without any reliance on medicine. In any case, his conclusion is as stated, that the acidosis is less troublesome with each successive fast in a given course, and that the obvious benefit of each fast becomes more pronounced as the treatment is continued, within reasonable limits.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF

SUPPURATIVE MONARTICULAR ARTHRITIS IN AN INFANT,

DUE TO *B. PARATYPHOSUS C.*

BY ARCHIBALD LANGWILL, M.B., F.R.C.S. EDIN.,
LATE TEMPORARY HOUSE SURGEON, PADDINGTON GREEN CHILDREN'S HOSPITAL.

THE following case is published on account of its extreme rarity.

A female infant, L. R. M., aged 11 months, was admitted to the Paddington Green Children's Hospital on May 18th, 1921, on account of a marked swelling in the region of the left shoulder-joint.

History.—She had always been a healthy infant up to about the end of March, 1921, when she developed whooping-cough. On April 27th she was very feverish, and had "continuous fits" from 5.30 P.M. till 8.30 P.M. At that time it was thought she was dying. Since then there have been no further fits, and the violence and the frequency of the bouts of coughing have gradually diminished. Breast-fed entirely since birth up till a little over a week before admission, since when she had been having several feeds of cow's milk in addition to the breast. A week before admission the mother noticed that the infant seemed disinclined to move the left arm, and that there was apparently a certain amount of pain occasioned when passive movements at the shoulder-joint were attempted. Next day the left shoulder region was swollen, and this gradually increased. No history of trauma beyond the severe convulsive seizures three weeks previous to admission. No history of diarrhœa recently or of hæmorrhage from skin or mucous membranes.

Family history.—Parents both alive and healthy. Neither has suffered from any serious illness. Two sisters, aged 3 years and 2 years respectively, also healthy.

Condition on admission.—Well-nourished infant. Temperature 99° F., pulse 152, respiration 45 per minute. On examination it was found that the left shoulder-joint was obviously uniformly distended with fluid. Fluctuation well marked. No actual redness or œdema of the overlying skin. Movements at the shoulder only slightly restricted, but when carried out passively seemed to cause the infant pain.

Operation.—On May 19th, after an exploratory puncture, chloroform was administered, and I opened the left shoulder-joint by the anterior route. On incising the joint capsule, which was tightly distended, about an ounce of a thick yellow pus was allowed to escape. This was aseptically collected for bacteriological investigation. Drainage of the joint was established by inserting a small piece of india-rubber dam, and hot fomentations were applied. Since the child was suffering from whooping-cough, the mother was allowed to take her home, with instructions to put the case at once under the care of her private medical attendant.

Pathology.—I am indebted to Mr. H. W. Perkins, pathologist to the hospital, for the following bacteriological report: "A thick yellow pus, in films of which are found a few Gram-negative bacilli. A free growth of this bacillus is obtained in pure culture. The organism is actively motile; it does not liquefy gelatin. Culturally, it presents the biochemical reactions of the salmonella group. Gas production in sugar media is feeble, and the fermentation of dulcite is slow. The organism is not agglutinated by 'Oxford' specific serums for *B. paratyphosus A*, *B. paratyphosus B*, and *B. enteritidis* (Gaertner). After daily subculture for a period of two weeks its cultural and serological characters remain unaltered. The identity of this bacillus was finally established by Lieut.-Colonel H. Marrian Perry, R.A.M.C., professor of pathology at the Royal Army Medical College, who very kindly undertook the further investigation of this organism. He found that it was agglutinated by his paratyphoid C serum to its full titre (1–5000)."

Remarks.

It is needless to emphasise the value of the notes of this case, when it is recollected that, in the first place, the recovery of *B. paratyphosus C* from even the stools or the blood is a very rare event, and in the second place, its recovery in pure culture from a suppurating joint—and this apparently as a de novo infection—must be almost unique. It is, of course, impossible to say where and when the causal organism gained its entrance to the blood stream, but might it not be permissible to assume some such relation as cause and effect between the change from feeding entirely at the breast to partial artificial feeding, and the joint infection very soon afterwards? The possibility of *B. paratyphosus C* having been "imported" by the father—as a "carrier"—from one of the theatres of war was considered, but on inquiry it was found that he had neither been abroad nor ever suffered from symptoms to suggest an infection by one of the enteric group of organisms. I may add that I have followed up the case, and have heard quite recently from the mother that the child is now in good health. The wound continued to discharge freely for about ten days, after which the amount of discharge rapidly diminished. The wound closed completely five weeks after the operation. According to the mother, not the slightest impairment of function of the affected joint remains.

I wish to express my indebtedness to Mr. D. C. L. Fitzwilliams, to whose ward in the hospital the child was admitted, for kindly granting me permission to publish these notes.

paying special attention to the urethra, preliminary to passing a catheter. Forceps are then applied and removed directly the head is crowned. Pressure with one hand over the sterile towel on the abdomen prevents the head receding. When the head is crowned a nurse injects 1 c.cm. of pituitrin deeply into the gluteal muscle. As soon as the child is born the cord is ligated; the child is then removed to another room so that its crying will not disturb the mother, who should be allowed to sleep quietly on, after having been made comfortable. I have always found the third stage quite normal in every respect.

It might be mentioned that at the commencement of the second stage I employ my time in applying hot fomentations to the perineum. These are wrung out of weak lysol, and serve the double purpose of sterilising the region and softening the tissues, thereby lessening the probability of a tear.

With regard to the vexed question of oligopnœa, I have only met with a few cases, in all of which the child spontaneously recovered without treatment of any kind. If wrapped in a warm blanket and left alone the baby will breathe normally in a minute or so. In one or two difficult forceps cases with a child born suffering from asphyxia pallida I have had resource to a hot bath and artificial respiration. The only deaths I have to record were twin premature babies—born at six months. Both breathed, but died shortly afterwards. The mother had only one injection, and the children would not have lived in any case.

Particular Advantages of Twilight Sleep.

Twilight sleep is of particular advantage in breech cases and in minor degrees of pelvic contracture, where it is desirable that the second stage should be prolonged to obtain satisfactory results. I have given it with conspicuous success in cases with heart disease, and I noticed that in his article on "Heart Disease and Pregnancy"[1] Sir James Mackenzie mentions that twilight sleep ought to be useful in such cases, but frankly confesses that he has had no experience of the treatment. In elderly primiparæ it is invaluable. One of its most striking benefits is in the appearance and feeling of well-being manifested by a patient after a long and difficult labour, which tends to endorse the absence of conscious suffering. Shock and exhaustion are largely avoided, and with their avoidance the long train of nervous after-effects and disabilities are mitigated if not entirely abolished. Surely the memory of an exhausting and agonising labour must leave in its wake a host of neurasthenic tendencies with a vivid dread of a recurrence of the event—modified though that dread might be by the knowledge that second children are less of an ordeal. Apart from economic reasons, a dread of this kind must adversely affect the birth-rate of the country.

For the busy general practitioner the scheme I have outlined above must often prove impracticable. The late Dr. F. W. N. Haultain speaks of good results obtained by leaving the injections to a responsible nurse, in telephonic communication with the doctor. The injections are given at stated intervals. The initial dose of scopolamine gr. 1/150 and morphia gr. ¼ is recommended, and thereafter scopolamine alone gr. 1/450 is injected every hour. "Although not scientifically correct," Dr. Haultain adds, "this method is sufficient to acquire the benefits required without danger." I would only add to this that the nurse should be instructed to miss an injection during any hour that the patient is heard to mutter at random, and that in a number of cases the dosage will be too small to be effective. In cases exhibiting an idiosyncrasy for the drug, who become unruly in consequence, a few drops of chloroform is all that is needed to quieten them. I have only met with one case who became so unruly as to require restraint, and I abandoned treatment on that account. Complete amnesia, however, was present during her case, and she remembered nothing of the labour.

There is no doubt that the effect of the drug varies in individuals, and I have found that, as a rough working guide, the larger the woman the larger the dose she requires. It is because of this variance in reaction in individuals that acute differences of opinion exist both in medical and lay minds as to the benefits of the treatment, and I would urge medical men before they condemn "twilight sleep" to consider the impossibility of giving an opinion without experience.

In conclusion, I would state that the more I give twilight sleep the more I like it, and I consider it to be the greatest advance in obstetrics since the employment of chloroform. That it mitigates actual pain and does not merely obliterate the memory of it is evidenced by the absence of screaming—the needle prick of the injection often passing unnoticed—and by the general demeanour of the patient, which is indicative of well-being as opposed to conscious suffering.

DOMICILIARY TREATMENT OF BONE AND JOINT TUBERCLE.

By W. C. RIVERS, M.R.C.S., D.P.H.,
TUBERCULOSIS OFFICER, BARNSLEY DISTRICT, WEST RIDING, YORKS.

THE lesson of the war (reinforcing as it does some neglected lessons of the past) that infection has been an overrated, and depressed individual constitutional resistance a much underrated, factor in the production of tuberculosis, will have had its effect upon the mind of the tuberculosis officer. He will easily deduce that the outstanding indication for action is the fact that the disease is twice or thrice as common in the working class as amongst the rest of the community; and that the chief prophylactic measure, therefore, is economic—namely, social amelioration. He will now feel assured that housing reform, even if practicable under present conditions, will never suffice of itself; will see that much of the time spent in examining symptomless adult "contacts," or in delivering lectures promising an early abolition of tuberculosis, was wasted. And all this realisation that prevention is really in other hands than his, will, or should, make him a Voltairian cultivator of his garden—lead him, that is, to concentrate for the time upon treatment.

In this line there seems at first sight little of much promise. The sanatorium the tuberculosis officer rarely sees; tuberculin is deservedly dropping out of therapeutic use; lung collapse applies only to a scanty proportion of one form of the disease; chemo-therapy as yet only to the small group of skin tuberculides. But there does remain something. Two years ago I left Alton after a two months' stay kindly allowed me by Sir Henry Gauvain, to study the Continental methods of treatment of osseo-articular tuberculosis of which he is so accomplished an exponent; for that period of time I have been applying the working knowledge there gained in the ordinary practice of a tuberculosis officer, and the improvement in one's results is striking.

Problem of Accommodation.

In old days the general practitioner used perforce to send hip or spine caries to a general hospital, or try to get such into one or two overcrowded special institutions. The former plan was desperate. The general hospital had not accommodation enough, and the folly of making out-patients of those needing before all else continued rest in bed in one posture, is evident. Yet, unfortunately, practitioners are still prone to this method of disposal. What often happens is that the case is sent first for diagnosis, or confirmation of diagnosis, and then goes on attending for treatment. When the National Insurance Act came into force, sanitary authorities engaged beds at a special institution, perhaps an orthopædic hospital. I have had good opportunity of comparing treatment by some orthopædists with treatment by surgical tuberculosis specialists, and have found that of the latter to be the better; mainly, I think, by reason of case of undoubted syphilis of the stomach in which the only symptom had been a sudden hæmatemesis.

(*d*) Stenosis. One case had already been quoted of pyloric stenosis. Mid gastric stenosis producing hour-glass stomach had been reported by Bensaude. This patient, who had lost 20 lb. within two months, recovered under treatment and even the biloculation disappeared. Stenosis of the cardia occurred in a case of Enriquez and Bensaude. There was no history of syphilis in this case—that of a woman, aged 35 years. Gastralgia, constant vomiting, and the loss of 80 lb. weight within 18 months, led to a screen examination which revealed a double stenosis occurring in the cardia and mesogastrium. Under specific treatment she gained 30 lb., but six months later began to lose weight again. Screening on this occasion showed no loculation of the stomach, but that the pylorus was incompetent and the duodenum greatly enlarged. The condition had then become one of the next type.

(*e*) Linitis. The example just quoted was the only one described by Dr. Monod.

(*f*) Tabes. This came within the scope of the paper only when there was a definite lesion of the stomach associated with tabetic crises.

Hereditary syphilis.—All the types described above might occur in hereditary syphilis. In children there were two special types, the symptoms of which were: (*a*) gastric hæmorrhage in the new-born; (*b*) chronic vomiting without acetonæmia.

Diagnosis.—This resolved itself into two questions, Was the stomach at fault? and Was the lesion syphilitic? In the elucidation of the latter question, the Wassermann reaction was helpful, and Dr. Monod had found Stern's reaction valuable: screen examination often revealed a characteristic picture. Where a portion of the stomach had been excised the presence of spirochætes could be demonstrated in definitely syphilitic lesions.

The action of potassium iodide provided a very useful test. In syphilis of the stomach the organ seemed to crave for potassium iodide, and rapid improvement usually occurred, whereas with other dyspepsias the drug aggravated the symptoms. There were, *however*, cases in which spontaneous cure occurred, and others where specific treatment was ineffectual.

The *treatment* he advised was the use of mercury, potassium iodide, and salvarsan. combined sometimes with tartro-bismuthate of potassium. The best treatment could only be settled by further experiment and experience. Surgical intervention was called for in certain cases, where there had been scar-tissue formation.

In conclusion, Dr. Monod said that while it could not be accepted that all cases of stomach derangement cured by specific treatment were definitely syphilitic, we should not forget that a number of otherwise uncontrollable dyspepsias were amenable to anti-syphilitic treatment.

Discussion.

Dr. J. W. McNEE said that he could add little to the clinical side of the subject, but would describe an unique example of syphilis of the stomach, which had been admitted to the wards of Dr. Sidney Martin, F.R.S., in University College Hospital. The patient was a man of 57 years, who had suffered from pain in the chest and abdomen of six months' duration. A provisional diagnosis of carcinoma of the stomach was made for the following reasons: there was a palpable mass in the epigastrium: free hydrochloric acid was absent in the gastric contents, while lactic acid was present. The Wassermann reaction was not carried out. Sudden perforation occurred shortly after admission and rapid death ensued from peritonitis. At the autopsy a large ulcer was found occupying three-fifths of the wall of the stomach, the only parts of the organ remaining free from ulceration being close to the cardiac end and close to the pylorus. The wall of the stomach in relation to the ulcerated area was greatly thickened. the thickness in parts reaching a diameter of three-quarters of an inch. Microscopically the condition closely resembled a scirrhous carcinoma, but it was noticed at the time that no secondary growths were present in the liver or neighbouring organs, and the lymphatic glands in the neighbourhood of the stomach were also free from metastases. On this account careful histological examination of the ulcerated area was carried out. In sections a condition strongly suggestive of syphilitic infection was made out, there being well-marked endarteritis obliterans of small arteries, and extensive round-celled infiltration along the vascular capillaries. In other places where the lesion appeared to be more acute abundant granulation tissue of a peculiar type, and of very active growth, was observed. A number of blocks of tissue taken from different parts of the ulcerated area were stained by Levaditi's silver method for the demonstration of spirochætes. In one block of tissue taken from an acute granulomatous area abundant spirochætes were found, morphologically identical with the *Sp. pallida*, having 8–14 regular curves. Dr. McNee exhibited the actual stomach, with microscopic and lantern slides demonstrating the various lesions and the spirochætes. This specimen appeared to be unique from the fact that the diagnosis was made by the discovery of the spirochætes. No signs of syphilis were found in any of the other organs.

Dr. A. F. HURST said that his experience of syphilis of the stomach was very limited, and he had only seen two definite cases, one of a gumma simulating carcinoma, the other being a syphilitic ulcer which simulated an ordinary duodenal ulcer. He had had the Wassermann reaction tested in at least 100 cases, when the diagnosis of syphilis was remotely possible. Nevertheless, the remarkable results of antisyphilitic treatment in the two cases to be described suggested that the Wassermann reaction should be tested in all doubtful gastric cases.

1. *Syphilis of the Stomach with Achylia simulating Duodenal Ulcer.*—The patient, a man aged 51 years, had had dyspepsia for 20 years with a five year remission. The symptoms were strongly suggestive of duodenal ulcer, pain three hours after food, waking him in the night, and relieved by a meal. A strict course of medical treatment, rest in bed, diet, and alkalies failed to improve him, and he was then sent to Dr. Hurst, who found almost complete achylia with an atonic stomach instead of the hyperchlorhydria and hypertonus typical of duodenal ulcer. The fasting gastric contents contained large numbers of leucocytes, and the stools occult blood. There was no history of syphilis, but a Wassermann reaction proved strongly positive, and a single injection of salvarsan resulted in so great an improvement that he refused further injections. He took an acid and pepsin mixture for some months, but had since had two further injections of salvarsan, and now appeared completely cured of symptoms, although the Wassermann reaction was still slightly positive.

2. *Gumma of the Stomach causing Pyloric Obstruction.*—This patient, a man aged 33 years, had syphilis in 1901. Eight years later he began to suffer from indigestion; his appendix was removed with only temporary relief. In 1911 he had pain in the right hypochondrium relieved by vomiting, with flatulence, wasting, and constipation. An X ray of the stomach revealed considerable delay supposed to have been due to a duodeno-jejunal kink. The following year X ray examination showed obliteration of the normal gastric outline in the pyloric half of the stomach. Mr. Peter Daniel operated and found a rigid pylorus without definite ulceration for which he performed a gastro-enterostomy with temporary improvement. Symptoms returned within a year, and on being called in consultation Dr. Hurst advised a Wassermann reaction, which proved positive. Three injections of neo-salvarsan proved completely curative of symptoms.

Mr. A. J. WALTON agreed that the frequency of syphilis of the stomach had been estimated variously by different observers. His experience of surgical gastric disease included 264 of gastric ulcer, 125 of duodenal ulcer, 125 of gastric carcinoma, 1 of sarcoma, and 1

A NOTE ON
GUELPA'S METHOD
IN THE TREATMENT OF GOUT AND GLYCOSURIA BY FASTING AND PURGING.

BY SIR HENRY LUNN, M.D., B.CH. DUB.

Dr. Guelpa's visit to the Royal Society of Medicine suggests to me to put on record the endeavours to combat various manifestations of gout in the one patient (myself) upon whom I have ventured to practise since I took my M.D. in 1887.

Thirty years ago, at the age of 32, I went to see my friend, the late Dr. Howard Barrett; I was suffering at the time of my visit from constant severe headaches, hæmorrhoids, and bad eczema. Dr. Barrett told me I was like "a volcano of gout ready to break out anywhere in any direction." He reduced my meat diet to very moderate limits with much advantage, but I was still pursued by gouty headaches, sleeplessness, and sluggishness of the liver.

Three years later I read Haig's "Uric Acid as a Factor in the Causation of Disease," and although Haig exaggerated the importance of uric acid in the causation of gout and other diseases, I found his book very valuable. In 1896, being still much troubled with gouty symptoms, I visited Tarasp, the waters of which resort contain a very large percentage of sodium sulphate. I was benefited greatly by a three weeks' course, which—together with Haig's views as to the value of sodium salicylate—led me to adopt a daily dose before breakfast of Carlsbad powders with 5 to 15 gr. (according to my condition) of sodium salicylate. I found also that small doses of potassium bromide with the salicylate had a remarkable and valuable influence upon my nervous system; these and a short sleep before dinner were necessary if I was to avoid bad nights and interference with my work. By these means I was able to keep down, within certain limits, the gouty tendencies which Dr. Barrett had considered so serious. Nevertheless, in Dec., 1899, Dec., 1900, Sept., 1903, Feb., 1906, and Jan., 1909, I had five prolonged attacks of acute tonsillitis and pharyngitis, followed each time by lumbago and severe erythema nodosum, which on each occasion laid me aside for periods from four to six weeks. These attacks have ceased since the adoption of prolonged fasts.

A First Fast.

In 1910 I read an article by an American in one of our monthly reviews on the fasting remedy. It was Easter Day. Immediately after reading the article I stopped eating for a fast of five days. On Easter Monday I had an 18-hole round of golf in the morning with much enjoyment, and in the afternoon attended to various matters. On Tuesday I had an exceptionally long day at business, 8.30 to 5.30, as there was no time occupied by meals. On Wednesday I commenced work in my office at 8.30, and after a very full day attended a dinner of the Isis Editors at Simpson's Tavern, where I spent the time in conversation, sipping Apollinaris Water meanwhile. I finished up at the Savage Club on more Apollinaris, getting home to Harrow in perfectly good form at 12.30 A.M. On Thursday I continued the fast, and on Friday and Saturday took milk for two days, afterwards returning to my ordinary diet, with my whole system immensely benefited by the experiment.

Systematic Fasting.

I read various American books, and in the following year took a nine days' fast on similar lines, drinking water copiously throughout, but only consuming during the whole period a pint and a half of milk divided into three glasses taken on three of the coldest days when I wanted additional fuel. Since that date I have tried every summer to put in a long fast, drinking only water during the warm weather, when the absence of fuel in the system could best be borne. I have also observed as far as possible a weekly fast for 11 years with great benefit. If I omit the weekly fast I at once suffer from a diminution of mental energy. The American school, represented by Allen of the Rockefeller Institute, did not recommend purgation with the fasting, and in common with all to whom I have spoken who have tried this treatment, constipation and a thickly-coated tongue were amongst the difficulties of the fast. In following years I gradually resorted to larger and larger doses of sodium sulphate to obviate these symptoms.

Treatment of Glycosuria.

In 1916 the anxieties of the war in business and domestic affairs caused my health to suffer. I was examined by my friend Dr. de Havilland Hall; going with him into his laboratory I was surprised to find that his test showed me to be suffering from glycosuria, which at that time amounted only to an excretion of 35 gr. of sugar per day. A carbohydrate-free diet with codeia sulph. for a short time, and a visit to the Alps, entirely removed these symptoms. My diet consisted of eggs, fish, green vegetables, excluding peas, cocoa with cream, and special biscuits of nuts, and a particular bean (kalaki), with butter ad lib. A similar attack in 1917 was quickly terminated by the same regimen and I had no recurrence until the summer of this year, when I had a sharp attack in consequence of special anxiety and strain in my home life.

Guelpa's Method.

In Paris, returning from our visit to the Spas, I called with a well-known London physician upon Dr. Guelpa, who was the first European to systematise the fasting treatment and the first physician to advocate extreme purging. He promulgated his views in 1908 and was met with vigorous opposition. His views were discussed in 1908 at the Therapeutical Society and the Society of Medicine in Paris. Laufer claimed that no invalid, no diabetic, would submit to three, four, or five days of absolute fasting combined with a daily purge. Burlureaux stated that reiterated purging might produce certain disorders and a nervous shock unfavourable to these patients, and Linossier maintained that if fasting, as we have known for a long time, gets rid temporarily of the sugar, it weakens patients and predisposes them to acidosis and to coma; and, moreover, that to stop glycosuria is not to cure diabetes, of which the presence of sugar in the urine is only one symptom. Contrary to the opinion of the American school of Allen who does not use drastic purges, but advocates adequate purges, Guelpa contends that fasting and diuresis do not expel the intestinal poisons which tend to produce auto-intoxication. He therefore concluded that purgative elimination of these poisons, and draining by osmosis of those that remained in the circulation, would largely increase the eliminating action of fasting and diuresis, and he recommended fasts of varying periods, not generally exceeding three days, with a morning dose each day of 400 g. (1¼ oz.) of sodium sulphate. Dr. Guelpa expressed his pleasure at meeting one who had come by his own experience, and without knowledge of Guelpa's methods, to very much the same conclusions, although the heroic doses just mentioned had not been adopted. Since leaving Paris I have had the opportunity of taking a steady course on these lines, fasting two days the first week, two days the second week, and two days the third, and have found that this course has been much more effective than any I have previously attempted. All sugar has disappeared and I am again returning to my usual health. Once each week I take 1¼ oz. of sulphate of sodium and fast completely for 36 hours, excepting for weak cocoa and cream. In the fourth week I fast two days.

My own personal experience may be of value, but I have no claim from general observation of a large number of patients to deal at length with this question. It was, however, of great interest to find that Dr. Guelpa—whose experience is enormous and whose methods have been so largely adopted in France—entirely corroborated my own findings. Dr. J. Laumonier, editor in chief of the *Revue de Chimiothérapie et de Médecine Générale,* in two very able

Hence arose the necessity of a simultaneous blood-urea estimation. This class of case gave a better operation risk than would be imagined from examination of the blood-urea alone. Thus in one of Mr. Everidge's recent prostatectomies, where the blood-urea was 57 and the *urea-concentration 1·93 per cent., rapid convalescence* without any symptom of uræmia occurred. In another case where the blood-urea was 131, but the urea-concentration was 2·14 per cent. suprapubic lithotomy had been performed with a good result. Amongst cases where the urea-concentration did not exceed 1·5 per cent. while the blood-urea figure fell within *normal limits, there was no single instance of recovery* after prostatectomy. The deaths were not all due to uræmia. As regards the technique of the test, Mr. Everidge withheld all fluids for 12 hours beforehand and gave half a pint of water immediately after the draught of urea-solution. Since the highest concentrations of urea in the urine had been found in many cases to occur in the third hour, it was now his custom to collect specimens of urine at the end of each of the three hours after the meal. This procedure also overcame the difficulties caused by the diuresis promoted by the urea, which, as a rule, had passed off by the third hour. It was unfortunate that the test could not be carried out in many cases complicated by digestive disturbance, as the meal was vomited; nor could it be accurately applied where suprapubic drainage had been established. An interesting point was that the urea-concentration generally rose temporarily after nephrectomy.

Blood-Urea Estimation.

The blood-urea figure was variable through wide limits in the same individual according to diet, and a single estimation might be most misleading. His attention had been drawn to this by noting the marked increment in the blood-urea during the few hours after the urea meal was administered for the urea-concentration test; this occurred during health and disease. In Mr. Everidge's experience blood-urea estimation fulfilled two important rôles: (1) an adjunct to the urea-concentration test (by eliminating an abnormally high "pressure head" of blood-urea which may be causing a high urine urea). (2) In distinguishing uræmia from other diseases clinically indistinguishable therefrom.

Results of Application of Urea-Concentration Tests.

Mr. SWIFT JOLY gave the results of the urea-concentration test as applied at St. Peter's Hospital to 64 cases of enlarged prostate. Of 23 cases where the urea concentration exceeded 2 per cent., 21 had been operated upon with two deaths. Of 14 cases with urea-concentration between 1·5 per cent. and 2 per cent. there was one death after operation. Of 13 cases in which the urea-concentration lay between 1·0 per cent. and 1·5 per cent. only five had been submitted to operation and one of these died; while four cases with a urea-concentration of less than 1 per cent. had been operated on without any death. The deaths in the first class of case (i.e., those with a urea-concentration exceeding 2 per cent.) were not due to renal deficiency. On the whole, therefore, this test yielded some indication as to the advisability of operation. In many cases, however, a low urea-concentration was accompanied by a large diuresis, so that Mr. Joly was inclined to think that the total quantity of urea excreted during the second hour of the test gave a more accurate indication of the renal efficiency. Certain precautions were always taken at St. Peter's Hospital. Every patient was kept in hospital for 24 hours on a standard diet before the test. As regards cases where nephrectomy or any unilateral kidney operation was proposed, the test could be applied to the urines from each kidney obtained by ureteral catheterisation. In cases of unilateral kidney disease, such as aseptic stone, hydronephrosis and other conditions, the urine from the healthy kidney always showed a higher urea-concentration than that from the affected side, and was not infrequently as high as 3 per cent.

Renal Function Tests in Surgical Cases.

Mr. FRANK KIDD said that there were two distinct classes of surgical cases in which renal function tests were applied: those in which the renal function as a whole needed investigation (for example, before prostatectomy) and those where the function of one kidney needed investigation before the other kidney was removed for disease. Mr. Kidd had employed at various times simple excretion tests, excretion tests combined with stimulation, retention tests (blood-urea), and the hæmo-renal index. As the result of his experience he preferred the following tests: (1) a dye test (indigo or phthalein); (2) the blood-urea test; (3) the hæmo-renal index.

Where prostatectomy was under consideration there was obviously no need to separate the urines, as only the effect of back pressure on the secreting substance of the kidney need be considered. When the renal efficiency tests indicated poor efficiency, Mr. Kidd performed a two-stage operation, and he considered that this involved less risk to the patient than catheter life. In performing the various tests he avoided the use of the catheter, which was undoubtedly dangerous; if urine could not be obtained by ordinary means he preferred the use of Pezzer's tube introduced suprapubically, as this involved less danger of infection. As regards the interval between the two stages of the operation, he thought it wiser to err on the side of waiting too long. Before nephrectomy the problem was different. Here, again, Mr. Kidd was averse to the utilisation of any test that necessitated prolonged catheterisation of the ureters for two reasons: (1) the danger of sepsis, and (2) because the introduction of the ureteral catheter reflexly affects the rate of secretion from the kidney. Quantitative tests applied to urine obtained were thus fallacious and the prolonged indwelling of a catheter inevitably produced ureteritis. In these cases Mr. Kidd relied upon a dye test combined with the hæmo-renal index, as estimated by the electrical conductivity of a drop of blood and of a single drop of urine from each ureteral catheter. He was inclined to think that the percentage of urea was a more valuable indication of the renal condition than the total amount of urea excreted. Mr. Kidd said that the colour test which he advocated had the immense advantage of being easily applicable at the patient's bedside. He did not advocate the above tests for the investigation of medical cases; for these the blood pressure, combined with ordinary clinical examination of the urine, supplied a more reliable indication of the efficiency of the kidneys.

The Need for Simple Tests.

Prof. H. MACLEAN said that renal efficiency tests must be simple if they were to be of any material help to the surgeon. By laboratory investigations it was possible to estimate the renal efficiency of any case, but the three tests advocated by him were easily applied, without complicated apparatus and without even putting the patient to bed. Prof. MacLean and his co-workers had applied the tests now on more than 15,000 occasions, and had found them efficient. The tests were (1) the blood-urea; (2) the urea-concentration; (3) the urea-concentration factor.

The Blood-Urea Test.—In interpreting this test the previous diet of the patient was most important. It was also found that the blood-urea normally increased with advancing age. Prof. MacLean emphasised that uræmia as a clinical condition had nothing to do with the urea content of the blood, and instanced a case where a patient, with a high blood-urea figure and clinical signs of uræmia, died of uræmia, in spite of the fact that the blood-urea was brought down to the normal figure by a carbohydrate diet.

Urea-Concentration.—In the interpretation of the urea-concentration figure, the amount of blood-urea and the question of diuresis had to be considered, but in general it could be stated that a urea concentration of 2·5 to 3 per cent. after the urea meal indicated efficient kidneys, while a figure of 2·0 to 2·5 per cent. indicated "good average" kidneys unless the blood-urea figure was very high. When the urea-concentration was less than 1·5 per cent. the kidneys were inefficient unless this low figure was due to profuse diuresis. In the latter event

A CASE OF
STRANGULATED OBTURATOR HERNIA.

BY A. ERNEST SAWDAY, M.B., B.S. LOND., M.R.C.S.

THE following case is particularly interesting in that it illustrates the common reluctance to diagnose a rare condition even in the presence of signs and symptoms which are strongly suggestive.

Mrs. K., aged 69, when first seen had been suffering from abdominal pain for four days. For the past three days there had been increasingly severe vomiting. The tongue was coated and the bowels had not been open for two days. An enema produced a fair result, but did not relieve the symptoms. The pain was ascribed to the lower abdomen and particularly to the left femoral region.

History.—Fifteen years ago pelvic colon resected for carcinoma. A few years later an operation for strangulated right inguinal hernia.

Examination.—Abdomen somewhat distended, but nothing palpable. Left femoral region somewhat tender on pressure. Tissues there appeared a trifle more resistant on palpation than at the corresponding point on the other side. Rectal examination negative. The possibility of an obturator hernia was considered, only to be dismissed in favour of obstruction by a recurrence of growth.

Operation.—On opening the abdomen turbid fluid escaped, and the apex of a loop of the lower ileum was felt passing through the left obturator foramen. This loop was very tightly nipped, but after some manipulation it was withdrawn into the abdomen. It was found to be a Richter's hernia involving nearly the whole circumference of the bowel, and a large patch on the anti-mesenteric border of the gut was quite gangrenous. Some six inches of ileum were resected and a side-to-side anastomosis performed. The patient did well for some days and the bowels were well opened on several occasions, but at the end of a week hypostatic pneumonia set in and she died two days later.

This case is typical of the text-book description of strangulated obturator hernia, which most frequently occurs in old ladies; the classical signs and symptoms of acute obstruction are accompanied by pain, slight tenderness, and resistance in the region of the femoral sheath.

Derby.

A CASE OF
DISCHARGE FROM THE UMBILICUS.

BY FREDK. JOHNSON, M.B. LOND., F.R.C.S. ENG.

THE following case is uncommon and merits record.

H. C., a railway plate-layer, presented himself complaining of a discharge from the navel of some two weeks' duration, accompanied with pain below and to the right of the spot. The patient was of a strong and robust build, and there were no symptoms referable to the intra-abdominal organs. By manipulation a clear and scanty serous discharge could be expressed from the umbilicus. An induration with a fairly well-defined margin, rather larger than a half-crown piece and somewhat tender, was detected below and to the right of the umbilicus. The induration was situated apparently in the muscular wall rather than in the skin or subcutaneous tissues.

The patient's general condition suggested nothing of an acute nature. He was taking holiday and wished to return to work after a few days. A soothing warm application was prescribed, and two days later the patient returned with the story that a hay or grass seed had been passed with the discharge. This statement at once afforded a clue to the case. I examined the navel more minutely and found a fine track leading in the direction of the induration. An ordinary director was passed into the sinus; on its withdrawal the groove of the instrument was found to contain a thick cheesy offensive material with which were mixed the sheath remnants of grass seeds. The patient volunteered the statement that he had been engaged during the summer in removing hay from a railway cutting. The subsequent course of the case revealed nothing noteworthy; more grass-seed débris escaped and the discharge gradually subsided and with it the swelling below the umbilicus.

It was clear that several dried grass seeds with their cuticular coverings had become imbedded in the folds of the umbilicus and, aided possibly by the barb-like character of the seed covering and the contractions of the subjacent muscles, had penetrated the surface layers of the abdominal wall.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SYPHILIS OF THE STOMACH.

AN occasional lecture on Syphilis of the Stomach was delivered on Nov. 23rd by Dr. GUSTAVE MONOD, physician to Vichy Thermal Hospital, Sir JOHN BLAND-SUTTON, President of the Society, being in the chair.

Dr. MONOD said that the question of syphilis of the stomach was of great interest, as the treatment and life of the patient depended on correct diagnosis. As early as 1834 Prof. Andral (Paris) taught the occurrence of this condition, and cases were recorded by Dieulafoy, Hayem, Fournier, and Pater (Paris 1907). At the present time with the more accurate means of diagnosis, numerous cases had been described by Smithies, Hemmeter (U.S.A.), Chiari (Germany), Hayem, Leven, Bensaude, and Florand (France). Among the few British authors who had mentioned this disease were Soltau Fenwick[1] and McDonagh.[2] Syphilis of the stomach might exhibit itself by sclerosis, gummata, or submucous infiltration. An excellent specimen of this third condition, showing the spirochætes in situ, was being demonstrated by McNee.

The *frequency* of this condition varied greatly according to the various authorities, but Dr. Monod thought that the figures were increasing. The English records were surprisingly low compared with the French and American ones. He wondered if this was due to the prevalence of syphilis in France. Or might it be that syphilis was diagnosed earlier in England and treated, thereby preventing complications such as that which he was now discussing?

The *clinical types* of syphilis of the stomach might be summarised as follows:—

(*a*) Neuralgic or chronic dyspeptic.

(*b*) Ulcer. A case was described by Prof. Fournier in which gastrorrhagia was stopped by treatment with potassium iodide. Soltau Fenwick said that 5 per cent. of gastric ulcers are specific, while other authorities said 10 per cent. (Engel) and 20 per cent. (Lang). A report at the last international congress of medicine in Strasbourg estimated 100 per cent! During the war Castaigne found eight positive Wassermann reactions amongst 40 cases of gastric ulcer in soldiers, and four of these were cured by antisyphilitic treatment. The ulcer might be due to thrombosis, to the breaking down of a gumma, or to gastro-radiculitis.

(*c*) Pseudo-cancer. Many cases in which syphilis had mimicked carcinoma were now on record. Hayem had reported a case in which a pyloric tumour in a man, aged 71, disappeared under antisyphilitic treatment. The same author also recorded the case of a man, aged 60, suffering from vomiting, cachexia, and hypoacidity, on whom he performed pylorectomy under the impression that the condition was cancerous. The patient recovered and remained well. Examination of the excised pylorus revealed only syphilitic infiltration. The question arose, would anti-syphilitic treatment have been as effectual? This question might be answered by the experience of Tuffier, who operated on a man, aged 35 years, for a supposed hydatid cyst of the liver. Operation revealed a large gumma and was not proceeded with. Anti-syphilitic treatment was given, but in spite of this stenosis of the pylorus developed for which gastro-enterostomy had to be performed later. The second operation revealed a pylorus encircled by dense syphilitic scar tissue. Florand reported a similar case: pain after meals, vomiting, and loss of weight accompanied by a palpable tumour led to a diagnosis of cancer. Operation in this case revealed a syphiloma of the left lobe of the liver extending to the pylorus. Gastro-gastrostomy, followed by anti-syphilitic treatment, resulted in a cure. Lemierre and Roulot-Lapointe had recorded a which he had recently discovered, while working on tests of pancreatic function. He had discovered that the kidney acted as a safety valve to the blood-sugar and that the urine normally contained the same concentration of sugar as the blood. In renal disease this correspondence no longer held, and the blood not infrequently contained three times as much sugar as the urine. The fraction $\frac{\text{blood-sugar}}{\text{urine-sugar}}$ therefore gave an indication of the renal efficiency. The test could be applied to a very small quantity of urine or blood, ½ c.cm. of either being sufficient. It was therefore particularly valuable when applied to the small quantities of urine obtained by ureteral catheterisation, and would in these circumstances give an indication of the functional activity of either kidney. By the employment of this test Dr. Wallis had been able on one occasion to indicate disease in one kidney when all other tests had given no indication of total renal inadequacy, and there were no clinical signs of renal disease. It was subsequently discovered that the kidney was the seat of a hypernephroma.

[1] THE LANCET, 1899, ii., 410.

[2] Venereal Diseases, 1920.

The Doubtful Adequacy of Pathological Tests.

Mr. Girling Ball said that during the past year the renal function tests he had employed were (1) the urea-concentration test; (2) the estimation of the urinary diastase; (3) the estimation of the blood-urea. In addition to these in some cases estimation of the normal urinary sugar had been carried out. From a review of the results, it became obvious that the clinical findings should always hold the first place in the judgment of the surgeon. In the majority of his cases the clinical findings and pathological tests agreed closely, but the one or two exceptions made him sceptical of the value of any pathological test.

Mr. Ball's cases were divided into two groups: (1) those of obstruction in the lower urinary passages, and (2) those of ureteric or renal disease. In the first group there were 12 cases of prostatic enlargement, two of them carcinomatous, which were not submitted to prostatectomy. Of the remaining ten four died, two from pulmonary embolism and two from renal suppuration. One of the patients who died of pulmonary embolism had only had the first stage of a two-stage operation performed, in recognition of the fact that he had had chronic obstruction and that his urine was of persistently low specific gravity, and despite the fact that the renal function tests were normal. Unfortunately, a post-mortem could not be obtained, so that it was possible that the diagnosis of pulmonary embolism was incorrect. After the suprapubic drainage he had developed symptoms suggestive of uræmia, but at no time was there any suppression of urine.

In the second group were 17 cases of ureteric and renal disease. In three of them both kidneys were diseased. When the disease was unilateral, Mr. Ball believed that if the combined excretion from both kidneys gave normal figures and the clinical findings showed that there was another kidney secreting urine normal to ordinary urinary analysis, the diseased kidney could be safely removed. The difficulties of obtaining urine from each of the two kidneys in such a manner as to make chemical examination satisfactory were great. The urinary sugar and urea tests had, however, confirmed the clinical findings, and were important as they could be carried out with small amounts of urine.

The Points of View of Physician and Surgeon.

The attitude of the physician and of the surgeon towards these tests appeared to Mr. Ball to be quite different. The former wanted to know the functioning power of the kidney from the point of view of prognosis, while the latter wanted an opinion as to whether he should perform an operation in the most adequate fashion, a modified operation, or whether he should operate at all. The surgeon wanted the test that would indicate the amount of renal reserve, and no such test had yet been invented. Further, the tests were all made under the best conditions with the patient in bed and the kidneys being called upon to do a minimum of work. It was well known that a man could exist with one kidney, and that he would stand the operation of nephrectomy provided the second kidney was sound, and it had been his practice to rely on clinical investigations to demonstrate the absence of disease in the supposedly sound kidney.

The discussion stood adjourned.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

Exhibition of Cases and Specimens.

A laboratory meeting of this Society was held at the London School of Tropical Medicine, Endsleigh Gardens, on Nov. 17th, Surg.-Rear-Admiral Sir P. W. Bassett-Smith presiding.

Specimens were shown by Dr. W. Broughton-Alcock, Dr. J. G. Thomson, and Prof. R. T. Leiper.

Major H. C. Brown, I.M.S., demonstrated a method to facilitate the isolation of bacilli of the enteric and dysentery group in dysenteric stools. By the addition of one part of high-titre specific agglutinating serum to nine parts of saline emulsion of a small portion of fæces, sedimentation of the particular agglutinated, but still living, organisms was obtained with separation from other intestinal bacteria. Withdrawal by pipette of a droplet of the sediment and plating on MacConkey's medium secured on incubation a high proportion of colonies of the infecting organism. Culture plates were shown with controls to demonstrate the efficiency of this method as applied to the isolation of *B. paratyphosus*.

Dr. P. H. Manson-Bahr gave an account of a case of amœbic abscess of the liver which had ruptured into the lung, and was eventually cured by large doses of ipecacuanha. Diagnosis was confirmed by the presence of cysts of *E. histolytica* in the sputum. Abundant growth of yeast fungi was obtained on cultivation from the sputum, and but for the finding of histolytica cysts might have been taken to point to a mycotic infection as the primary cause of disease.

Dr. Manson-Bahr also showed microscopical preparations and drawings illustrating the pathology of bacillary dysentery.

Dr. G. C. Low and Dr. Elizabeth O'Driscoll showed pathological specimens: (1) From a fatal case of blackwater fever in which a positive Wassermann reaction had been obtained. Reference was made to similar instances, suggesting the possibility of a syphilitic factor in the causation of some cases of blackwater fever. (2) From a supposed case of malaria, in which malignant endocarditis and splenic infarcts were found on post-mortem examination. Other examples of the erroneous diagnosis of malaria were quoted as by no means infrequent. (3) Trypanosomes in the cerebro-spinal fluid and blood of a case with a previous history of malarial fever, in which the course of the trypanosome infection was characterised by slow cerebration, peripheral neuritis, and raised temperature.

Dr. Andrew Balfour showed specimens of two poisonous sea-fish, or Laffe, from Mauritius: (1) *Pterois volitans* (Linnæus); (2) *Synanceia brachio*, var. *verrucosæ*. Both possessed formidable poisonous dorsal spines, the venom from which, on puncture of the skin, gave rise to severe local abscess and septicæmia, with serious symptoms of violent pain up the limb, great restlessness, and occasionally fatal results. The remedy applied by the Mauritian fishermen was claimed to be effective, but its composition was kept secret by the natives.

Mr. A. Bacot and Dr. J. A. Arkwright showed stained preparations of the various forms of *Rickettsia melophagi* found in the sheep ked—*Melophagus ovinus*.

Squadron-Leader H. E. Whittingham gave an account of cases of sand-fly fever in Malta, from of leather-bottle stomach. Whenever possible microscopic examination of excised portions had been made, but the Wassermann reaction had not been carried out as a routine.

Linitis Plastica.—In his own series there was only one case of leather-bottle stomach, too extensive for gastrectomy. Post-mortem investigation showed this to be a case of carcinoma, and the London Hospital had found no example of the syphilitic variety of linitis plastica.

Carcinoma of the Stomach.—It was well known that syphilis occasionally produced a tumour very like an early cancer. Bird believed that syphilis was to be suspected if the tumour was succulent looking and almost opalescent, and if the omentum showed white unexplained scars. Some of the cases of supposed carcinoma too extensive for gastrectomy, which recovered completely after gastro-enterostomy or even without any interference, might have been syphilitic, and he (Mr. Walton) had met with three such cases where the operation had been performed by another surgeon. Among his gastrectomies there was no evidence of syphilis on microscopic examination.

Chronic Gastric Ulcer.—The majority of reported cases of syphilis of the stomach resembled chronic gastric ulcer. In the London Hospital Pathological Institute only one case of a syphilitic lesion of the stomach had been demonstrated at over 12,000 post-mortems. He thought it probable that the variation in the figures might be due to the fact that some of the ulcers occurring in syphilitics were not in themselves specific but simple peptic ulcers. It should be remembered that a positive Wassermann reaction was not definite evidence that the lesion in the stomach was syphilitic. The appearances of a syphilitic ulcer were said to be as follows: they were deep with much surrounding infiltration, often causing much distortion of the stomach; perigastric adhesions were common, and widespread scarring occasionally caused obstruction necessitating operation.

As regards symptoms, the general health appeared to suffer considerably and loss of weight was marked. Hæmorrhage occurred just as in the cases of chronic ulcer. According to Downes, free acid tended to be diminished. In his (Mr. Walton's) experience syphilitic lesions of the stomach were rare.

The Histological Diagnosis of Syphilis.

Prof. H. M. **TURNBULL** said that the histological diagnosis of syphilis was even more difficult in the stomach than in any other organ. If the changes typical of syphilis elsewhere—namely, infiltration with plasma cells, lymphocytes and eosinophils, endarteritis and endophlebitis, and the presence of multinucleated giant cells—were to be accepted as evidence of a syphilitic origin of a gastric ulcer, then all, or almost all, chronic peptic ulcers would have to be classed as syphilitic. There was definite evidence, however, against such an extreme view, and Prof. Turnbull thought, in view of Dr. McNee's success in demonstrating the *Spirochæta pallida*, that this would provide the only positive evidence of the syphilitic origin of any gastric lesion. At the Pathological Institute of the London Hospital they had examined portions of 713 stomachs from the operating theatre without finding any evidence of syphilis. Syphilis of the stomach was undoubtedly very rare; in 13,000 post-mortems at the hospital one doubtful case only had been found, although they had constantly been on the look-out for it. A few apparently typical "gummatous ulcers" of the stomach proved on histological examination to be chronic peptic ulcers with a growth of a Gram-positive streptothrix in their bases. The one doubtful case was that of a female patient, aged 30, who died after a miscarriage at the sixth month, which had been preceded for three days by profuse hæmatemesis. Post mortem abundant evidence of syphilis was obtained in the aorta, the scarring of the soft palate, vaginal orifice, &c., and the positive W.R. of the blood. There were a number of enlarged fibro-caseous glands in relation to the bronchi and trachea, and an enlarged upper lumbar gland on each side. A large irregular ulcer involving the posterior surface of the body and fundus of the stomach, with a granular yellowish-grey base surrounded by a raised border honeycombed with small ulcers, showed on histological examination changes typical of intense gummatous inflammation. Gummata were found in the liver. This case was still under investigation and Prof. Turnbull thought it doubtful, since the distribution of the glandular enlargement was typical of tuberculosis spreading from the hilum of the left lung, and because he had not found spirochætes on microscopical examination of no less than 14 different portions of the stomach stained by Levaditi's method.

SECTION OF UROLOGY.

A MEETING of this section of the Royal Society of Medicine was held on Nov. 24th, Sir **THOMAS HORDER**, the President, being in the chair.

Mr. **JOHN EVERIDGE** opened a discussion on

RENAL FUNCTION TESTS.

He said that the tests chiefly employed by himself were (1) dye-excretion; (2) forced urea-excretion; (3) urea-retention (blood-urea). About 600 cases, mostly surgical, had been investigated by him.

Dye-Excretion.

Two dyes had been employed, phenolphthalein and indigo-carmine. By the former, quantitative, and by the latter qualitative estimation of the renal function was attempted. Indigo-carmine was employed to give an estimate of the relative working of each kidney. By its use the frequency of jets from the ureters as seen with the cystoscope was made obvious and a hidden ureter easily discovered. Phenolphthalein, in the opinion of Mr. Everidge, could not be relied on to give a very accurate estimate of the total renal function. He had found it give only 66 per cent. of accurate results when used as a preliminary investigation before operation (chiefly prostatectomy) on the lower urinary tract. In one case where colour came through in five minutes, and 36 per cent. of the dye was excreted in the first hour, the patient died after the second stage of a two-stage prostatectomy; post mortem very little renal tissue was present. When used as a test of relative kidney value, phenolphthalein gave about 54 per cent. of results which were thought to be accurate since they coincided with those obtained by alternative tests and from the clinical phenomena. In many cases the test gave a doubtful result and in 15 per cent. the results were quite misleading.

One case, a female, who had suffered for five years from symptoms suggestive of a right-sided intermittent hydronephrosis, gave the following results after the injection of 6 mg. of phenolphthalein and catheterisation of the ureters: From the right kidney the colour came through in ten minutes, while none appeared from the left kidney in half an hour. Pyelography immediately after revealed no abnormality on the left side, while the right presented a definite piecture of hydronephrosis. Mr. Everidge showed radiograms of this case. Subsequent operation revealed stenosis of the upper end of the right ureter, and the patient made an excellent recovery in spite of the apparently low efficiency of the left kidney as estimated by the phenolphthalein test.

Mr. Everidge added that the personal equation entered largely into the reading of any dye test, and that his personal reading might be open to criticism. The presence of blood or other pigments in excess in the urine obviously vitiated this test.

Urea-Concentration Test.

Although at first somewhat sceptical that so simple a test could be efficient, Mr. Everidge had found this test demonstrate increasing or decreasing renal efficiency with remarkable accuracy. Certain precautions had, however, to be taken, and of these a 12 hours' abstention from food and drink before the test was essential. In certain cases with a high "pressure head" of urea in the blood, urea appeared to be forced through the kidney as MacLean had suggested.

---

[1] THE LANCET, June 19th, 1920.

would doubtless throw additional light on other morbid conditions.

Discussion.

Prof. E. P. **Cathcart** referred to the importance of the study of the respiratory exchange. Unless such investigations were well and thoroughly done, they were valueless. All the apparatus in use had flaws and some many flaws. Of the apparatus recently introduced for general clinical use most was of little use and of limited application. For accurate results methods such as the closed circuit or gas analysis must be used. Physiologists believed this study to be one of the most fundamental. It gave clues to changes taking place in the living organism and enabled us to learn more completely what was the normal and what abnormal. In Prof. Cathcart's opinion the new methods would throw much light on many problems but would not be adaptable to clinical use on a large scale.

Dr. **Leonard Findlay**, in congratulating Dr. Fleming on his work, said his own observations on the condition known as infantile atrophy had led to certain conclusions as to the cause of the condition which were shown to be wrong by Dr. Fleming's observations. Dr. Fleming had done experiments in a case of obliteration of the bile-duct in which there was practically no metabolism of fat. In this condition the respiratory quotient was lowered by the fat, showing that free fat interfered with carbohydrate metabolism. Towards the understanding of questions of nutrition, the study of the respiratory quotient was of great value. Finkelstein taught that an infant should be fed according to the expected weight and not according to actual weight, and Dr. Fleming's results showed that this was correct. No doubt other theories and other problems in nutrition would be helped by these studies.

Mr. **James Taylor** made a communication on

Stovaine Anæsthesia.

He described the method of giving stovaine and the care to be taken in its administration, limiting his account to his own experiences in something over 500 cases. He used only the heavy variety, and while believing some of the other drugs are safer, found that none gave such a perfect muscular paralysis, and this was of great importance in abdominal cases. Mr. Taylor always used stovaine and glucose and all his injections were given in the lumbar region. He considered stovaine to be the most perfect method of blocking the afferent nerves and protecting the patient from shock, in other words, of obtaining anoci-association. A fall of blood-pressure occurred just after the injection and this might in rare cases be alarming. In Mr. Taylor's opinion operations associated with much shock could be more successfully performed under spinal anæsthesia than with any other anæsthetic. In ten disarticulations at the hip after intrathecal injection all the cases recovered except one, where the collapse after a railway smash was extreme. Twelve consecutive cases of Wertheim's operation were performed without a death; in one of these cases the whole rectum from the pelvic colon downwards was also removed. Another group of cases where stovaine had definite advantages was that including intestinal obstruction in the presence of much abdominal distension. In these cases the abdominal muscles were so completely paralysed by the injection that the difficulty of closing the abdomen so often experienced was completely done away with, and, moreover, there was less tendency to paralysis of the involuntary muscle of the intestine. Mr. Taylor referred to several of the disadvantages of the method, such as the trouble of injection, usually slight, and the difficulty of procuring the proper mental atmosphere during the operation. This, however, introduced less strain on the operator than that of working with general anæsthesia where the administrator was not highly skilled. The administration of morphine and hyoscine would send the patient to sleep during the operation. Mr. Taylor said that the greatest objection to stovaine was the initial fall in blood pressure and apparent collapse. This might be overcome by injection of pituitrin or inhalation of a little ether. In elderly and feeble people, those with serious renal disease and those suffering from recent loss of blood or anæmia the condition of the patient might become alarming. The duration of the anæsthesia was variable and the higher the site of the operation, the shorter time it lasted. In the upper abdomen it lasted about half an hour and in the lower abdomen about one hour. Fifteen minutes after the administration of stovaine and glucose no further extension upwards took place.

ULSTER MEDICAL SOCIETY.

A meeting was held on Nov. 17th, Dr. **Robert Hall**, the President, in the chair.

Prof. T. **Walmsley** read a paper on the

Origin of Man.

He dealt first with the broad outlines of evolutionary progression, and drew attention to the experimental or tentative forms which have existed at all levels of the animal kingdom. On this basis he speculated as to whether there had been tentative forms of man. The history of man was inextricably mixed with all the problems of the Quaternary or Pleistocene period. Prof. Walmsley described the period of Neolithic culture, and then the different phases of the late Palæolithic age, the peoples of the two being compared and contrasted, and the probable present-day representatives of the Magdalenian and Solutrean phases were pointed out. He defined the Mousterian period, and described Neanderthal man, special reference being made to the size of the brain and the nature of the teeth. Prof. Walmsley supported King's view that Homo Neanderthalensis was a distinct species, or at least something more than a variety of modern man. He outlined pre-Mousterian periods, and placed in them Heidelberg man, Java, Piltdown, and Galley-Hill, indicating the relationship of Heidelberg to Mousterian man. Pithecanthropus was an earlier offshoot, in some ways more different and in some ways less so, from modern man, while the Galley-Hill skull, though distorted, was modern in its general form, but primitive in detail. Prof. Walmsley concluded, therefore, that they were early offshoots from the human stem, that the differences between them and modern man were greater than the differences between modern races, and that they should probably be classed as different species.

A discussion followed in which Prof. W. J. **Wilson**, Dr. H. L. **Kisack**, Prof. J. A. **Lindsay**, and others took part.

The **Secretary** announced that the annual dinner of the Society would be held on Dec. 8th.

LIVERPOOL MEDICAL INSTITUTION.

A meeting of this society took place on Nov. 17th, Dr. J. E. **Gemmell**, the President, in the chair, when Dr. **Haward Bywater** read a short paper on Malarial Eye Complications.

Dr. **John Hay** described three cases of

Spontaneous Pneumothorax.

In each case the patient was a male in the early twenties. The pneumothorax was left-sided, and recovery was uneventful; there was no effusion and there was no pyrexia. He discussed the question of diagnosis, pointing out its extreme difficulty in some cases in the absence of an X ray report. In his opinion this was due to the frequent absence of the more dramatic physical signs so definitely associated with pneumothorax. In a closed dry pneumothorax there was a different grouping of signs, and thus recognition was less easy than in a case where amphoric breathing, metallic tinkling, and metallic echo were present. Dr. Hay discussed the character of the pain in these cases, and referred to its remarkable similarity to cardiac pain.

Prof. MacLean advocated repeating the test immediately by giving a further 15 g. of urea. The initial diuresis usually disappeared after the second meal, and the figure then obtained would be reliable.

The Urea-Concentration Factor.—This was the fraction :—

$$\frac{\text{Number of mg. of urea in 100 c.cm. of urine}}{\text{Number of mg. of urea in 100 c.cm. of blood}}$$

and represented the power of the kidney to concentrate the waste products from the blood. The normal figure for the factor was 60 to 80. When the factor was about 40 the outlook for any surgical operation was poor, and with a factor of 20 almost hopeless. By the consideration of the three tests he had found no difficulty in prognosticating the risk of major surgery on the urinary apparatus, but he wished to emphasise the fact that results depended not altogether on renal efficiency but also on the rapidity and dexterity of the surgeon.

Certain Fallacies and Corrections.

Mr. **CYRIL A. R. NITCH** said that Prof. MacLean had elaborated a technique which was so simple in application and so simple to understand that with a knowledge of the different normals the surgeon required very little experience to form a good working conception of renal efficiency or deficiency. Mr. Nitch had employed the following tests during the last three years: (1) the percentage of urea in total amount of urine passed in 24 hours by a patient on a normal hospital diet; (2) the urea concentration in second and third hour specimens after a dose of 15 g. of urea; (3) the blood urea-concentration; (4) the clinical signs of renal functions, such as the degree of thirst, the appetite, particularly for meat the condition of the tongue, and the colour of the skin. Any single test might be misleading, but when all these were taken together a very reliable indication of the condition of the kidneys was obtained. In fact, he had recently shown Prof. MacLean a tabular statement of over 100 cases subjected to operation, and after reading the results of the tests Prof. MacLean had given a forecast in every case. There were, however, certain fallacies :—

1. The percentage of urea in 24 hours was normally about 1·5 per cent. in hospital patients, but the figure depended entirely on the diet, and would naturally be higher on a diet containing an unusual amount of proteins.

2. The urea-concentration test might be modified by diuresis, as already pointed out by previous speakers.

3. The amount of urea in the blood on an ordinary hospital diet was normally 20-40 mg. of urea per 100 c.cm. of blood, but the amount was subject to some variation according to the amount of protein in the diet. Prof. MacLean had already pointed out that it was useless to attempt to prevent uræmia by confining a patient to a carbohydrate diet.

4. The clinical signs were, in Mr. Nitch's opinion, the most valuable of all, and when a patient exhibited a typical clay-coloured complexion, a beefy tongue, and complained of thirst or a disinclination for meat, he would not allow any chemical test to influence him in favour of operation. On the other hand, if the clinical signs were good, while the chemical tests were below standard, he would be guided by the clinical signs. Mr. Nitch instanced a case where prostatectomy had been performed successfully, although the chemical tests were bad, while the patient's general condition would seem to indicate fair renal efficiency.

He added that the diastase test had been performed as a routine in all his cases, but that the results had been so variable that he had ceased to place any reliance on it.

Mr. Nitch's conclusions, based on a series of 118 cases comprising urethral strictures, lithiasis, diseases and neoplasms of prostate, bladder, and kidneys, were that the three tests mentioned were simple and efficient; they were harmless to the patient, and could be applied to every variety of urinary disease; they gave more accurate information than any others at present in use; and that the clinical signs of renal function were of great importance and should never be overlooked.

Renal Function as a Unit.

Mr. **J. B. MACALPINE** referred to the different points of view from which physicians regarded this subject, and the numerous tests which they had invented with the object of differentiating the various non-suppurative inflammations of the kidney. Much of the work of the physician had a histological basis, but in the surgical field the kidney function was to be regarded as a unit, and the tests applied were designed to supply indications in prognosis and treatment. Mr. Macalpine discussed two tests: the phenolsulphonephthalein test and the blood-urea test. This former test represented the kidney function in excreting urea and similar substances, the excretion of phenolsulphonephthalein being comparable with that of several substances, amongst them urea. On the other hand, the amount of blood-urea indicated the "head" of urea necessary before which it could be expelled through the kidney. The two tests should, and did, as a rule in actual practice, show parallel results. It was, however, well known that the normal human being had approximately three times the amount of renal tissue necessary for existence, and that signs of renal failure only set in when about two-thirds of the kidney tissue had been destroyed. But when the activity of the kidney was limited by disease then the organ had to work more and more continuously in order to meet the requirements of the body. Toxic products only appear in the blood when the whole of the safety margin of renal tissue had been destroyed. Renal degeneration had therefore advanced a long way before the blood-urea test gave any definite indication. The phenolsulphonephthalein test gave earlier indications of renal degeneration, although, as already stated, the indications by the two tests ran practically parallel.

Mr. Macalpine thought that these artificial tests were more variable in prostatic disease than an examination of the symptoms. He believed that the effect of the tests had been to widen out the rungs of the uræmic ladder so as to make it possible to observe more clearly the position occupied by any one patient in the scale. Further, he thought it possible to mark out arbitrary figures on the scale indicating: (1) the upper limit of the normal variation for blood-urea; (2) a line below which a one-stage operation might be safely done and above which a two-stage prostatectomy was advisable; and (3) a line which would lie at the entrance to the danger zone. He assumed that 40 mg. per 100 c.cm. represented the upper limit of blood-urea in healthy people. He regarded 50 mg. as the limit for one-stage prostatectomies and 75 or 80 mg. as the level at which the prognosis should be guarded. After urinary decompression operation the activity of the kidney was still further depressed and blood-urea figures naturally increased. After this preliminary depression a reaction or positive phase occurred and an adequate study of the blood-urea curve at this period was of the greatest importance. Nothing could be more haphazard than to submit a patient to the second stage of operation until it was known that the blood-urea had fallen to normal. Further, an immediate post-operative fall in the blood-urea should not tempt one to proceed with the second stage until it was certain that the fall was not due to the post-operative restriction of urea-forming bodies in the diet. Renal fibrosis might result from back pressure, but might also arise from sclerotic lesions of cardiovascular origin. The fall of blood-urea after decompression was liable to be very slow when fibrosis was due to the latter cause. Mr. Macalpine had on one occasion waited as long as five months before performing a successful prostatectomy.

In cases where it was desirable to avoid operative interference, systematic readings of the blood-urea should be made to see to what extent, if any, the kidney was deteriorating. In such cases, the phenolsulphonephthalein test should be avoided since it involved the use of the catheter with the attendant risk of sepsis. In that type of renal tubercle, with extension to the bladder, rendering ureteral catheterisation impossible, Mr. Macalpine regarded the blood-urea test as the most satisfactory means of estimating the efficiency of the second kidney.

A New Test.

Dr. **R. L. MACKENZIE WALLIS** said he had had experience of several of the tests already described. He wished, however, to speak mostly about a new test

Reviews and Notices of Books.

ESSENTIALS OF MENTAL MEASUREMENT.

By WILLIAM BROWN and GODFREY H. THOMSON. Cambridge Psychological Library. Cambridge University Press. 1921. 21s.

THIS book is a successor to one published by Dr. Brown in 1911, the old material standing without much change, but being supplemented by five new chapters from the pen of Dr. Thomson. The two authors write separate prefaces, and Dr. Brown appears to reserve his opinion on certain views of his colleague. The book falls into two parts, on Psychophysics and on Correlation. Of the former, a chapter of 12 pages is given to the nature of mental measurement, but is restricted to the case of sensory thresholds. A highly condensed chapter is allowed to the actual methods of measuring these, one to Skewness of Frequency Distributions, and one to the Elementary Theory of Probability. The second part of the book, which is about equally long, deals successively with the following topics: Introduction to Correlation; Mathematical Theory of Correlation; Influence of Selection; Correction of Raw Correlation Coefficients; the Theory of General Ability: and a Sampling Theory of Ability. There are in addition several useful mathematical tables.

If we compare the book with its chief existing English rival, the "Mental and Social Measurements" of Thorndike, it becomes obvious that it aims at being fundamental and concise, rather than at bringing the exposition within the compass of very weak mathematicians. If the ground the authors cover omits much that many would like to see there, this is chiefly due to their assigning a relatively large space to certain questions in which they are especially interested. One of these is the correction of raw correlation coefficients. Here they strongly oppose the corrective formula suggested by Prof. Spearman, but unfortunately their position is mainly based on some curious slip in the value of the "probable error" concerned, this being given by them of the wrong order of magnitude. Still greater space is devoted to the theory of ability, in respect of which Dr. Thomson strongly combats the view that the correlations found between the results of mental tests should be attributed to one "general factor." But it is to be regretted that he could not have managed to introduce some notice of the basal objections to his argument published by Spearman in May, 1920.[1] The theory proposed by Dr. Thomson in place of that of the general factor is one of "sampling." According to this, the said correlations are due to "a number of factors at play in the carrying out of any activity such as a mental test, these factors being a sample of all those which the individual has at his command" (p. 188). Other topics receiving full, but by no means excessive, notice are the Criterion of Goodness of Fit of Psycho-physical Curves and the calculation of correlations by ranks instead of by measurements. Here Dr. Brown, though still maintaining a cautious attitude, has at any rate widely departed from the very pronounced hostility of his earlier edition.

The book may be thought to attempt to combine two very different aims. The first is to supply a general text-book on the methods of mental measurement, whilst the second is to write a keenly controversial pamphlet, of which the chief topic is not general methods, but special ones applied to special matters. On the other hand, these matters do no doubt stand at present in the very forefront of experimental work, and the authors are among those whose views will be received with the highest degree of interest. Their words ought to and will be widely read. The polemical trend is tempered by generous eulogies of adversaries and the style of writing is admirable.

PHYSIC AND FICTION.

By S. SQUIRE SPRIGGE, M.D. Camb., F.R.C.S. Eng. London: Hodder and Stoughton. 1921. Pp. 307. 12s. 6d.

THIS book ranges over a wide field of medical and paramedical interests—the medicine of the novels to which the author confesses an addiction, the probability of being able to poison anyone without being found out, what "out-of-date" means in medicine, eugenic marriage certificates, Cornelius Agrippa—one might almost say it treats *de quibusdam aliis* as well as *de omnibus rebus*.

Running through the book are two main propositions. The first is that medicine is progressive and constantly advancing, sometimes by slow accretion, sometimes by one of those fundamental leaps which does not simply add one more piece to knowledge, but multiplies all previous knowledge a hundredfold. The difficulties of the poisoner have gradually become greater and greater with the advance of chemistry, culminating perhaps for the present in the admission of the validity of physiological tests for aconitine with which Sir Thomas Stevenson hung Lamson. But Lister transformed the surgical world by one great bound. One way and another this progress, quick and slow, is going on all the time, and compels medical education and medical practice to enlarge their borders in proportion. The second, less appreciated but no less important, thesis is that the doctor has now definitely ceased to be a member of a craft whose mysterious and exclusive information is doled out to the public in pontifical decisions. There are questions whose medical bearing is as obvious as their general importance, though answers to them cannot be dictated by medicine. The medical factor has now intruded into so many matters of public interest that an increasing number of thoughtful men and women are compelled to solve a certain number of medical problems either for themselves or in coöperation with doctors. The abandonment of a distinctive dress by medical men means something more than a desire for personal comfort or unobtrusive modesty. It means that doctors are not set apart from an educated public, the whole of which must and does play its part in the promotion of healthiness. No one can doubt the importance of this change, least of all those who read it in Sir Squire Sprigge's urbane and moderate statement and who will realise in his volume that it is possible to be desperately serious without being in the least bit solemn—indeed being sometimes very much the reverse.

TUBERCULOSIS.

Tuberculosis of Children. By Prof. HANS MUCH, Director of Department for Science of Immunity and for Research of Tuberculosis at the University of Hamburg. Translated by Dr. MAX ROTHSCHILD, California. New York: Macmillan Company. 1921. Pp. 156. 12s. 6d.

IN this book on tuberculosis of children Prof. Much takes a long time in getting to the children, but when he does so he is much to the point. Only the last half of the book is devoted to children; the first half is a general survey of the problems of immunity in relation to tuberculosis. In both parts the author is remarkably lucid, and, considering the great complexity of the subject discussed, some readers will be tempted to raise the question: Is the author able to discuss these problems with clear-cut precision, as if most of them were already solved, because his is a master mind, or is his clarity of view simply due to his following only his own lines of thought, and using blinkers in regard to theories and hypotheses which clash with his own? He does, indeed, discuss the views of other authorities, but most of them, to judge by his verdict, must be strangely misguided persons. The satirical exclamation, "How these Christians love one another!" would seem to be applicable to present-day pathologists as well as to early Christians. On Spengler's I.K. the author passes the judgment which a spironema had been isolated by blood culture on to Noguchi's medium, and the modification of blood-agar (Wenyon, v. infra) in six out of 26 patients. The blood was cultivated on the first day of fever, and controlled by ordinary broth cultures. On the sixth day of incubation the resulting growth was used for the inoculation of volunteers, including himself, who developed typical symptoms of sand-fly fever, slight elevation of temperature, malaise, aches and pains, and anorexia. The blood counts showed a well-marked leucocytosis. One case from which the spironema was obtained developed jaundice and febrile relapses on the eleventh and twenty-second days, the jaundice being possibly due to a mixed infection. A specimen of the cultivated spironema was shown by dark-ground illumination.

---

[1] Psychological Review, 1920, xxvii., 159–172.

Dr. C. M. **WENYON** demonstrated a culture-medium for protozoa and other organisms, consisting of a 10 c.cm. mixture of 1 part of nutrient agar to 9 parts 0·85 per cent. saline, cooled after sterilisation to 50° C., to which were added 20 drops of blood obtained with aseptic precautions from the ear of a rabbit by the paraffin method. This medium was less complicated than Noguchi's, and had been found of practical value for the cultivation of *Leptospira hæmorrhagica*, *Leishmania donovani* and *tropica* at 24–30° C., trypanosomes and flagellate organisms such as *Embadomonas intestinalis*. Hogue's egg medium for the cultivation of *Trichomonas* and *Embadomonas* was also described.

Dr. **WENYON** also showed a number of mice, whose blood, as the film under the microscope demonstrated, was heavily infected three months previously with *Trypanosoma equiperdum*, the cause of the disease known as "dourine" or "mal du coit" in the horse, donkey, dog, and rabbit, but less pathogenic for rats and mice. In the mice shown the trypanosome infection had disappeared after infections of "Bayer 205," and the mice were now in perfect health.

Dr. A. C. **STEVENSON** demonstrated some microscopic specimens for diagnosis.

Dr. **ALDO CASTELLANI** and Dr. M. **DOUGLAS** showed cultures on glucose-maltose and glycerine, agar and carrot of a monilia fungus, *Hemispora rugosa*, isolated from the tonsils of a case of tonsillitis, which, in the light of the cultures obtained, was regarded as tonsilo-mycosis. Following inoculations of the fungus into a rabbit, the monilia was recovered from the heart's blood, spleen, liver, and kidney.

Dr. S. H. **DAUKES** demonstrated the collection made by Prof. Woodland of a series of Indian cobras (*Naia tripudians*), which had been preserved in formalin and showed variations in colour markings.

Dr. P. A. **MAPLESTONE** showed a smear stained with Leishman from an ulcerating granuloma on the inside of the cheek of a female Australian aboriginal, aged 22, showing large mononuclear cells heavily infected with organisms associated with granuloma pudendi, also free extracellular forms. The condition, very rare in the mouth, cleared up rapidly with intravenous injections of tartar emetic.

Dr. J. W. S. **MACFIE** and Prof. **WARRINGTON YORKE** showed a specimen of urine from a case of paroxysmal hæmoglobinuria indistinguishable from that passed during an attack of blackwater fever, and also specimens of blood from the same case showing autolysis. The explanation of the autolytic reaction depended on complement splitting; the reaction was not given by blood from blackwater fever patients.

Dr. **MACFIE** and Prof. **YORKE** also showed, from specimens illustrating the minute anatomy of *Oxyuris equi* (Schrank, 1788) and *Enterobius vermicularis* (Linnæus, 1758), that these belonged to quite separate type species. They exhibited also a blood film of a rat showing a small spirochæte obtained from a Gold Coast dog; the organism was regarded as identical with *Sp. laverani* (Breinl and Kinghorn, 1906).

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

A MEETING of this Society was held on Nov. 18th.

Respiratory Exchange in Health and Disease.

Dr. G. B. **FLEMING** made a communication on the Practical Application of the Determination of the Respiratory Exchange in Health and Disease. He outlined what was meant by the respiratory exchange by physiologists and pathologists, and explained the principles of direct and indirect calorimetry. The latter method was the one employed in his observations, when he used a closed circuit apparatus connected with which was a movement recorder. In order to fix a standard the basal metabolism was first determined. After much work this has been fixed for adults at 28 calories per kilo per 24 hours, or 950 calories per square metre of body surface per 24 hours. The difficulty in the case of infants was very great; the figures for very young children might not be strictly accurate, but were near enough for practical purposes. Dr. Fleming showed tables illustrating the basal metabolism at various ages and the influence of various factors thereon. In considering the practical application of this work, Dr. Fleming referred to Cathcart's studies of food requirements in the recruit undergoing training, and then compared the caloric requirements of men engaged for eight hours a day in various industrial pursuits with the requirements of an active boy of from 1 to 15 years old. The more arduous the occupation, the higher the metabolism. In certain diseases careful studies had been made and some valuable facts had been ascertained. In diabetes mellitus the respiratory quotient was low, and this proved that in spite of a high sugar content of the blood sugar could not be metabolised. It had been shown also that the metabolism in diabetes was carried out at an extravagant rate. Consequently as full a diet as possible should be given, other factors which might contra-indicate such a diet being taken into consideration. In exophthalmic goitre the metabolism was carried on at an excessively high rate, while in myxœdema and cretinism it was very low. The internal secretion of the thyroid seemed to have the power of stimulating metabolism. In a cretin under Dr. Fleming's observation there was a basal metabolism of 378 calories per 24 hours before thyroid treatment; after thyroid treatment for eight days the basal metabolism had risen to 482 calories per 24 hours. Recently Dr. Fleming had been studying infantile atrophy on similar lines and he outlined various conceptions as to the cause of this condition, and explained how he had tested the hypothesis that the fats, although absorbed, might not be utilised. From the figures obtained he had shown that the atrophic infant could burn fat. Dr. Fleming demonstrated diagrams which appeared to show that the metabolism was not carried on at an extravagant rate. In adjusting the figures it was found that the actual weight of the marasmic child when used for the calculation gave erroneous results, and that up to a point the calculated weight-for-age was the correct figure. This was accounted for by the fact that until 35 per cent. of expected weight has been lost the wastage had been at the expense of metabolically inactive tissue, fat, and carbohydrate, but that below this figure there was actual tissue wastage. One outcome of the investigation was that infants should be given quantities of food suitable for their expected weight—i.e., their age—rather than their actual weight. Dr. Fleming referred to observations of heat output in fever, and to the making good of loss by feeding. In conclusion he claimed that the study of the respiratory exchange allows us to prescribe a diet suitable for various forms of industrial or athletic activity, and to the varying requirements of the human organism from extreme youth to old age. In disease it had afforded knowledge concerning the derangement of metabolism in diabetes, exophthalmic goitre, myxœdema, infantile atrophy, and fever, and further use of these methods individuals, and tests for identification. The second portion describes the methods to be employed in manipulating the various classes of medicinal products to make them separable in accordance with this scheme. There is ample internal evidence that the volume has been written by one with much experience in the analysis of drugs and medicinal preparations. In a future edition Mr. Fuller may see his way to be a little more precise and amplify such expressions as "agreeable" or "disagreeable" odour.

The book will be useful to those who are concerned with the chemical examination of pharmaceutical products.

A French-English Dictionary for Chemists. By AUSTIN M. PATTERSON, Ph.D., formerly Editor of *Chemical Abstracts.* London: Chapman and Hall, Ltd.; New York: John Wiley and Sons, Inc. 1921. Pp. 384. 18*s.*

THIS book forms a companion to the German-English Dictionary for Chemists by the same author, reviewed in THE LANCET of Dec. 29th, 1917. This volume also is concise and easy of reference. We have found remarkably few errors and those not important. For example, *trognon* is not the core of a cabbage but the stump. To the explanation of *primeur*, "early product," might be added "or fruit." *Epuisé* also means "out of print." The inclusion of terms such as roi, reine, baronne, chevalier, seigneur, and monsieur seems unnecessary, and the American spellings of "thru" and "thoroly" appear strange. But apart from these trifles the compilation is unusually accurate, and the paper, binding, and printing are excellent.

Handbook of Chemistry and Physics. Eighth edition. By CHARLES D. HODGMAN, M.S., Assistant Professor of Physics in Case School of Applied Science; assisted by MELVILLE F. COOLBAUGH, M.A., Professor of Chemistry in Colorado School of Mines; and CORNELIUS E. SENSEMAN, M.A., Color Laboratory, United States Bureau of Chemistry. London: Chapman and Hall, Ltd. 1921. Pp. 711. 24*s.*

THE eighth edition of this book of over 700 pages contains a mass of accurate and useful information. That a large portion of the physical data is culled from the Smithsonian Tables is a guarantee of reliability, and there are few instances where one looks in vain for numerical values for the physical or chemical constants which have been experimentally determined. The arrangement of the book as a whole makes it easy to find the data required; possibly, however, it would have been better to place the definitions of the physical quantities and the characteristic chemical formulæ before, instead of after, the data pertaining thereto. On the whole, the subject-matter is rigidly chemical or physical, a few pages only being devoted to what are called Laboratory Arts and Recipes. The five pages devoted to the solution of problems in chemistry and physics do not enhance the value of the book. There are two and a half pages devoted to the functions, uses, and composition of foods which are obviously inadequate as an account of this wide subject. The volume, though large, is handy, and is equipped with an index covering 17 pages.

JOURNALS.

RIVISTA D'OSTETRICIA E GINECOLOGIA PRATICA. September, 1921. Anno III. Published by Prof. F. Montuoro, Palermo.—This is the official organ of the Sicilian Obstetrical and Gynæcological Society. The present issue contains an original article by Prof. Romolo Costa, director of the School of Obstetrics and Maternity of Novara, on Some Objections to Partial Symphysiectomy. These objections, which are four in number, are refuted by the author. He states that: (1) There remains no doubt whatever that partial or superior symphysiectomy in cases of pelvic contraction opens the way for the passage of the fœtus, and has its chief application in simple flat pelves where the true conjugate diameter is not below 75 mm. (2) As regards the permanent effect of the operation, in none of the women operated on was there any bony regeneration of the osseo-cartilaginous wedge taken out. (3) Out of seven women operated upon none of them showed any disability in walking as soon as they left their beds, usually about the tenth day. (4) There was no fear of any septic infection of the joint.—Dr. C. Calcaterra, of the University of Pavia, describes five cases of transperitoneal suprapubic Cæsarean section. He claims that this is the operation of election owing to the possibility it affords of ensuring exclusion of the uterine opening from the peritoneal cavity, and for its greater facility, simplicity, and rapidity of technique, while it possesses all the advantages of the extra-peritoneal method.—Dr. A. Buscemi, of the Obstetric Clinic at Florence, describes two cases of hepatic carcinoma occurring in pregnancy, one complicated by cardiac disease and ankylostomiasis, the other more advanced but pure—both in the first six months. The pregnancy exerted an unfavourable influence on the clinical course of both patients. In the case where it was the sole lesion there was rapid progress of the disease with effusion into the pleura; in the other case the aggravation was not so manifest until after parturition.—A number of pages are devoted to extracts and reviews, both Italian and foreign, and a brief article treats of subjects interesting to nurses trained in this branch.

HEALTH AND EMPIRE.—We have received the first issue of a monthly journal (price 6*d.*) issued by the National Council for Combating Venereal Diseases. In a prefatory note Lord Gorell hopes that it may play a valuable part in concentrating activity and formulating public opinion in the antivenereal campaign. An editorial article deals with the information which now flows in from European public health departments. Broadly speaking, it appears that Holland along with this country rely upon the voluntary principle, while Scandinavian countries, our own Dominions, and America avail themselves of certain compulsory powers. Outside this country the question of prophylaxis has not become acute. Dr. F. N. K. Menzies deals with the provision of hostels in London, without which no venereal disease scheme can be regarded as complete. Description is given of the efforts being made for amending the Merchant Shipping Act in order to remove from the seafarer the disabilities from which he suffers when he contracts venereal disease. The present position of affairs at Constantinople is described; the presence of destitute Russian refugees in addition to a congested permanent population of Greeks and Armenians has led to an amount of prostitution which is a menace to the public health. It is hoped that an International Red Cross Commission on public health will deal with a situation which has become a serious anxiety to the armies of occupation.

Corrigendum.—In an annotation last week dealing with the memoir of Prof. Howard Marsh, we alluded to him as Vice-Chancellor of Cambridge University. We learn, however, that he was already over age for that position when appointed Master of Downing College.

DAVID LEWIS EPILEPTIC COLONY.—At the annual meeting of the supporters of the David Lewis (Manchester) Epileptic Colony, held in Manchester on Nov. 25th, it was stated that the average number of colonists in residence was 356, the highest in the colony's history. The beds provided for four army men nominated by the Ministry of Pensions had been fully occupied. The occupations found for many of the colonists on the farm had proved most beneficial to them. Dr. Alan McDougall stated that drugs still took only a minor part in the treatment of their colonists; amongst patients seeking admission to the colony were persons to whom anti-epileptic drugs had been given over long periods without much success. Almost all the colonists were improving in health, and were happier than they were in their previous surroundings; some became so much better that they were able to return home and earn their own living.

Mr. R. C. Dun read a paper on

Undescended and Misplaced Testicle.

He reviewed the experimental and clinical work done on the ætiology, physiology, and pathology of the condition, and sifted the evidence regarding the spermatogenic and internal secretory powers of the undescended and displaced testicle. Mr. Dun discussed the bearing on these functions of the various operative procedures, and detailed the technique of the many operations suggested for the condition, giving results of operations in his own cases. He drew the following conclusions from his study of the subject. (1) Early operation is not advisable on account of the natural tendency for a testicle undescended at birth to descend into its normal position during the first years of life. (2) The associated presence of a hernia does not call for early operation. (3) The age selected for operation should be from 8 to 10 years. Testicles undescended at that age are unlikely to descend naturally, and symptoms—pain and attacks of orchitis—very frequently develop at this period. (4) Retained testicles which cannot be palpated should not be subjected to operation. (5) An undescended testicle should never be removed, on account of its possible spermatogenic power and its certain internal secretory power. (6) Abdominal replacement is not to be recommended as it is proved experimentally to destroy the spermatogenic function, should any be present, though the internal secretory power is retained. (7) Transplantation into the scrotum is the operation of choice. It can be successfully performed without endangering the vitality of the organ in the majority of cases where an undescended testicle is palpable.

SOCIÉTÉ DE THÉRAPEUTIQUE DE PARIS.

At a recent meeting of this Society MM. Pissavy and Touvay communicated a paper on the Treatment of Hæmoptysis by Pituitary Extract, in which they reported their observations on 15 cases of considerable hæmoptysis in pulmonary tuberculosis treated by intramuscular or intravenous injections of the extract of the posterior lobe of the hypophysis. They maintained that with the exception of artificial pneumothorax there was no method so effectual for checking hæmoptysis. Although in the great majority of cases the cessation of hæmorrhage was immediate, it was not always permanent. Not infrequently the hæmoptysis recurred after an interval of a few days and a fresh injection was required. The intramuscular route was often inadequate, and the intravenous route was alone reliable. One c.cm. of pituitary extract in 10 c.cm. of normal saline was injected slowly into the vein, five minutes being taken for the operation so as to avoid any shock. The most probable explanation of the action of the drug was that it caused an increase of the coagulability of the blood (Emile-Weil and Porak).

Mr. A. Richaud read a paper on the Posology of Cicutine Hydrobromide, in which he stated that as the results of observations in man and experiments in animals the toxicity of this salt was not so great as had hitherto been supposed. He had given one dose of 10 cg. subcutaneously or 15 cg. in two doses. Some signs of intolerance were observed when 16 cg. were injected at once.

In a paper on the Treatment of Gonorrhœa by Lymphotherapy Mr. S. Artault de Vevey reported 18 cases of gonorrhœa, 11 of which were in men and 7 in women, successfully treated by lymphotherapy—i.e., by intramuscular injection of the patient's serum obtained by the application of a blister.

Mr. R. Lautier read a paper on the Treatment of Gonorrhœa by Cedar-Wood Oil, in which he stated that he had treated cases of acute and chronic gonorrhœa with or without prostatitis, cystitis, vesiculitis, and orchi-epididymitis by administration of cedar-wood oil. The doses ranged from 2 to 8 g. a day. The dose was at first 2 to 3 g. and was gradually increased to 25 to 30 cg., the maximum dose being continued until recovery was complete—i.e., when the following requirements were fulfilled: (1) Disappearance of all discharge. (2) Disappearance of all filaments in the first jet of urine passed on getting up in the morning. (3) Disappearance of all subjective symptoms in the patient. Mr. Lautier's conclusions were as follows: (1) Cedar-wood oil was very well borne by the patients, even in such large doses as 6 to 8 g. a day. It did not cause any digestive disturbance, renal reaction, lumbar pain, or albuminuria, which cannot always be avoided with sandal-wood oil preparations whatever their degree of purity. No nervous symptoms were ever observed, such as vertigo, headache, excitement, or depression. (2) In acute gonorrhœa the various oils of cedar wood have a rapid action, cure being all the more readily obtained the earlier treatment is commenced. The previous use of antiseptic injections seemed to delay recovery. (3) In cases of gonorrhœa treated exclusively by cedar-wood oil from the commencement of the disease no urogenital or general complications were ever observed. (4) In cases of old-standing gonorrhœa which were refractory to all other treatment, a very rapid cure was sometimes obtained by the use of cedar-wood oil. In other cases it had to be given regularly for one and a half to two months to obtain a permanent cure. A few chronic cases proved refractory even to large doses of cedar-wood oil. These failures were exceptional with the essence of *Juniperus virginiana* or *Bermudiana*, and more frequent with the essence of *Cedrus atlantica*. (5) In cases of prostatitis, cystitis, vesiculitis, and orchi-epididymitis a rapid cure was obtained, except in cases where the gonococcus was associated with other micro-organisms, when 1 or 2 g. of hexamethylene tetramine were required to obtain a satisfactory result.

Mr. Lautier also read a paper on the Special Action of Cinnamate of Soda in Tuberculosis, in which he came to the following conclusions: (1) Cinnamate of soda definitely increases the output of urine, the increase amounting to one-third of the normal amount of urine passed in the 24 hours. (2) If before treatment the urine passed is deficient in urea and rich in uric acid, urates, and phosphates, after a few days' treatment the urine shows the following changes: The urea is increased to the normal amount, and the uric acid and urates are diminished in proportion to the increase in the urea. The phosphates are much diminished, and their elimination tends to return to normal. (3) If before treatment the patient's urine is normal, it undergoes no change in the course of treatment. (4) If before treatment one of the elements in the urine is excreted below the normal amount, the amount excreted tends to return to normal under treatment. Cinnamate of soda thus proved to be a mild diuretic and a regulator of the metabolism of nitrogenous substances and phosphates in the tuberculous organism. The gain in weight shown by the patient was mainly due to this action.

Mr. A. Claret read a paper on the Treatment of Anaphylactic Symptoms of Alimentary Origin, in which he stated that after unsuccessful treatment of this condition by various other drugs, he gave hexamethylene tetramine by the mouth, being guided by the following considerations: (1) The drug raises the blood pressure and increases its viscosity, these conditions, as Lumière has shown, tending to inhibit the development of anaphylaxis. (2) Insufficiency of the liver and kidneys, on which this drug has a selective action, creates a condition favourable for the development of anaphylaxis. Rapid recovery followed administration of uroformine in doses of 1 to 1½ g. daily.

Mr. Henry Bourges reported a case of *B. coli* Septicæmia in a child, aged 11, cured by subcutaneous colloid therapy.

ROYAL CANADIAN INSTITUTE.—At the next meeting of this institute, to be held in Toronto shortly, Lieut.-Colonel R. McCarrison will give an address on Diet and Malnutrition.

RONTGEN SOCIETY.—A general meeting will be held on Tuesday, Dec. 6th, at 8.15 P.M., in the Institution of Electrical Engineers, Savoy-place, Victoria Embankment, London, W.C. A paper on Some Investigations on Transformer–Rectifier Sets for X Rays will be read by Mr. M. A. Codd and a note on X Ray Tubes Connected in Parallel will be communicated by Mr. C. E. S. Phillips. Members wishing to read papers, show apparatus, or lantern-slides, are requested to communicate with the Hon. Secretaries, Dr. E. A. Owen, The National Physical Laboratory, Teddington, Middlesex; and Dr. Russell J. Reynolds, 140, Harley-street, W. 1.

A WEST SUSSEX SANATORIUM.—On Nov. 18th, Lord Leconfield opened the West Sussex County Council's Sanatorium near Chichester. The Council has purchased Aldingbourne House, a fine Georgian mansion standing in a well-timbered park of about 120 acres, and converted it into an institution for tuberculosis patients. There are 10 wards accommodating 44 patients, and in the grounds there are revolving shelters for 15 patients. The total cost of the scheme has been approximately £40,000, but the average price per bed has been reduced by the grant from the Government, and the county council has placed the figure at £500 per bed. Of the 120 acres, the county council has reserved 35 acres for the sanatorium requirements, and the remaining 85 are being utilised for small-holdings.

phases of the pandemic, a result in general agreement with that of PEARL. Dr. VAUGHAN next considers the history of influenza between 1893 and 1918 and goes carefully into the date of first appearance in 1918. He is inclined to trace the origin of the pandemic to America and to attribute its dispersiveness and virulence to movements of individuals and masses from one part of the world to another, whereby the partly adapted parasites become planted, as it were, into new soil, and the original equilibrium is disturbed—quoting the actual words of THEOBALD SMITH. The results of a sampling inquiry, similar to but more detailed than that undertaken by Dr. J. NIVEN and the Ministry of Health, resemble those of the English investigators, but Dr. VAUGHAN had materials for a consideration of racial and occupational susceptibility. The latter revealed no significant selection; as to the former it would seem that the Irish suffered less than other races—a contrast to their high mortality and morbidity rates from tuberculosis. Evidence of a relation between overcrowding and attack rate was hardly more striking than in England, but the following figures are remarkable: Of 360 persons occupying the same bed as a patient, 166, or 45·2 per cent., were infected; of 303 occupying the same room but not the same bed, 59, or 19·5 per cent., were infected; of 1064 members of the family of a patient but not belonging to one of the two previous categories, 273, or 22·3 per cent., were infected.

On the important subject of immunity, Dr. VAUGHAN was led to think that previous attack conferred no protection against the 1920 recurrence, a conclusion compatible with the results of the English inquiry, from which some protection against an autumn attack appeared to be conferred by the summer attack of 1918. Both sets of observations agree that the absence of any enduring immunity is an important factor in the explosiveness of primary influenza. The monograph ends with an appeal for further study. Influenza will surely return, Dr. VAUGHAN writes; he gives his reasons for asserting that there will be mild epidemics within the next few years, that later another pandemic will arrive, and that after this will come pandemics in succession. This is not an assertion made for flesh-creeping purposes, but a deduction from observation. In 1918, as in 1889, we were caught unprepared; let us do our utmost to prevent the recurrence of the tragedy; to delay is to lose the valuable information gained during the last two years. The future is not without well-grounded hope, but success will not be achieved until we have a much deeper understanding of the epidemiology of influenza. We think that the results reported by Dr. VAUGHAN, together with those of the Ministry of Health, justify a conclusion more definite even than these words convey. It is clear that influenza is in a different epidemiological class from that which contains small-pox and typhoid and that it has affinities with typhus on the one hand and pneumonic plague on the other. Small-pox and typhoid are epidemic diseases which, wholly apart from any general sociological factors, can be absolutely controlled. Their complete control is sadly impeded by ignorance and incompetent or selfish local authorities; the intellectual problem itself has been solved. Typhus and plague are in a different class. Of the former we may predicate with certainty that it will always become epidemic when the general standard of life has fallen to a critical value: of the latter we can say that a low standard of life, plus an unknown x, must be realised. The optimist hopes that influenza is more nearly akin to plague than to typhus, and that the x may be unmasked and prove to be a something which we can control here and now. The pessimist, focussing his attention upon the known factor, will be of opinion that a sinking standard of life, underfeeding, unemployment, overcrowding—conditions now characterising so large a proportion of the inhabitants of Europe—must sooner or later bear fruit which even the epidemic intelligence service desiderated by Dr. VAUGHAN will be unable to nip in the bud.

◆

Noise and its Cure.

NOISE is a serious evil in industrial communities. Continuous exposure to loud noises may lead to a sense of weariness that impairs working capacity more quickly than does severe muscular fatigue. It thus tends to lower output and so to raise the cost of production. From the economical point of view noise may therefore be regarded as exercising the same malign influence upon production as inefficient management, poor light, bad ventilation, or excessively long hours. This was, in brief, the message of Prof. H. J. SPOONER'S Chadwick Lecture delivered at Blackburn on Nov. 21st—to combat the noise plague, whether in our city streets or in our workshops and factories, and we are grateful to him for initiating a public movement for its removal. As Dr. DAN MCKENZIE has pointed out in "The City of Din," civilisation is noise, the more it progresses the noisier it becomes, and he has pictured Nature's desperate remedy of producing a human race devoid of hearing in order to protect the brain from the damaging effects of overwhelming auditory stimuli. The fact is that while noise may be tolerated, if not ignored, by healthy people at their best, the majority are not in a condition of bodily and nervous health to resist the irritation and consequent weariness induced by a long continuance of loud noises. It is not only the naturally hypersensitive CARLYLES who suffer, for few long-distance travellers by rail are altogether exempt from a fatigue which is probably due as much to the incessant bombardment of the brain by massive auditory stimuli as to any other factor. Over and above the effect of noise upon the general nervous system, there is the deleterious influence exerted directly upon the hearing-organ of workers in noisy occupations; and the list of occupations causing noise deafness at the present day is a long and increasing one. Hitherto, it must be confessed, the general attitude towards the evil of din, whether in the workshop or in the street, has been to regard it as inevitable, and to seek mitigation by the personal use of antiphones or ear-plugs.

But—and it is well to state it frankly—din, even in an industrial milieu, is not inevitable. We need go no further than to the modern motor-car to realise that when quietness in machinery, essentially noisy in its working, is of marketable value, the genius of engineering will ultimately succeed in supplying that quality. The difference between the smoothly running, almost silent automobile of 1921 and its fussy predecessor of 1900 is a measure of the preference given by purchasers to a noiseless vehicle. Now if, as Prof. SPOONER suggests, quietness in a factory can be shown to have an economic value, then we may reasonably anticipate that it will be forthcoming. Even now "quiet running" is beginning to figure more and more in the advertisements of engines other than those of the internal combustion type. Fortunately, apart from intentional reduction of noise, the natural evolution of modern engineering is tending in the direction of electric transmission in that it ". . . . is entirely devoid of any biological justification." A little further on he says of the same preparation that ". . . the agglutinating bodies which are supposed to be present in the red blood-cells . . . so far have had a most mystic existence in science." The author's opinion of the arguments in support of Maragliano's serum are summed up in the sentence: "Very crude ideas!" Marmorek fares little better, and his theory as to the nature of the tuberculin reaction is dismissed with: "This opinion is without foundation and has been proven wrong by me." Friedmann's turtle vaccine is also discussed unfavourably. After the storm provoked by all this iconoclasm, the reader is guided into the calm and safe waters of treatment by partial antigens. The author admits that it has been most difficult to disentangle the conflicting views and experiences with regard to tuberculin, but ". . . out of this chaos of varied opinions have developed the convincing and unshaken theories which are the results of the latest research." There follows an account of Prof. Much's partial antigen treatment. With regard to the possibilities of prophylactic vaccination on Deycke-Much lines, the author admits reluctantly that the proof of its usefulness would, of course, have to be furnished by statistics, but a little further on he adds plaintively, "Statistics have ruined many a possibility." Supporters of Much and his school may find in this half of the book a useful summary of his teachings. Others, who credit the author with a vividly creative and frolicsome imagination, are not likely to change this opinion.

While the first half of this book is a reflection of the author's vocation, the second half represents more or less an avocation, and is certainly the more instructive of the two. The modern view that in childhood the disease usually takes the form of hilus tuberculosis is accepted as correct. Prof. Much holds that pulmonary tuberculosis is secondary, as a rule, to disease of the glands in the hilus region. As for pleurisy in childhood, he regards it not as a primary tuberculous lesion, but as a comparatively late sequel to tuberculosis of the bronchial glands.

The author is to be congratulated on his translator, who has most faithfully reproduced the tone as well as the more material contents of the book. A few may consider this tone too perky and truculent; but most will probably enjoy the book from cover to cover.

Domiciliary Treatment of Pulmonary Tuberculosis. By F. RUFENACHT WALTERS, M.D., B.S., M.R.C.P. Lond., F.R.C.S. Eng., Joint Tuberculosis Officer for Surrey; late Physician Crooksbury Sanatorium and Mount Vernon Hospital for Consumption. London: Baillière, Tindall and Cox. 1921. Pp. xii. + 290. 12*s.* 6*d.*

IN the preface to this book Dr. Rufenacht Walters states that his object has been to furnish the practitioner with a compact and reliable guide to the treatment of pulmonary tuberculosis. He has succeeded in this object. In spite of its modest dimensions, it would hardly be an exaggeration to apply the term "encyclopædic" to this book; the author has condensed nearly all the modern literature, and much—too much—of the back literature of the subject into a wonderfully compact digest. With regard to remedies which have been tried and discarded, such, for example, as the intravenous injection of formaldehyde, it seems a pity that they should figure even briefly in this work. The practitioner is often a busy man, and he may have more than enough to do in mastering remedies which have survived the ten-year test. In his discussion of such remedies as Maragliano's serum the author omits to give his personal opinion; yet this is just what the practitioner wants to know. In some cases it is certainly possible to read between the lines that the author's account of a remedy is of the nature of an obituary notice, but he is unfortunately too considerate of the feelings of others to damn their work outright as valueless. Here and there, however, there is no mistaking his opinion, and in rationing his review of Much's partial antigens to exactly one line and a half, he conveys more to the reader than if he had let himself go. It is interesting to note that the author regards tuberculin ". . . as a remedy of the first importance." At present this is not the fashionable verdict on tuberculin, and the author shows no little courage in defending what might seem to many a lost cause. But as he is probably more familiar with the literature of tuberculosis than anyone, his opinion carries weight.

Tuberculosis and How to Combat It. By FRANCIS M. POTTENGER, A.M., M.D., LL.D., F.A.C.P., Monrovia, California. London: Henry Kimpton. 1921. Pp. 273. 10*s.* 6*d.*

Dr. Pottenger's book, he tells us, is published at ". . . the solicitation of my patients in order to put in a permanent form talks which have been delivered to them from time to time." From start to finish this work is characterised by sweet reasonableness, and the author has taken pains to explain carefully the reasons for the various rules he lays down for his patients. The book is worth reading both by doctors and patients, for it contains many useful hints as to their mutual relations.

CHEMISTRY.

Die Arzneimittel-Synthese auf Grundlage der Beziehungen zwischen chemischem Aufbau und Wirkung, für Aerzte, Chemiker und Pharmazeuten. Von Dr. SIGMUND FRÄNKEL, A.O. Professor für Medizinische Chemie an der Wiener Universität. Fünfte, umgearbeitete Auflage. Berlin: Verlag von Julius Springer. 1921. Pp. 906. M.276.

THE fifth edition of this voluminous and comprehensive book is a further enlargement of the previous one of 1918. The literature of the subject is now incorporated up to May, 1921. The new matter deals mainly with the subjects of taste and of quinine and arsenic compounds. The book is now so full of details that it is more of the nature of a dictionary than a general account of the subject; the mass of detail tends to smother the descriptions and makes the reading wearisome. The book is written on the unvarying German plan. There is a general section consisting of three chapters on the theory of the action of drugs, both inorganic and organic, with special reference to the part played by the individual chemical groups in the compound in the physiological action. A fourth chapter deals with the changes of organic substances in the organism. In the special section (14 chapters) a description of the numerous preparations employed as antipyretics, narcotics, alkaloids, antiseptics, purgatives, diuretics, &c., is given. The large index is useful and well compiled.

The book will be of service to those interested in the chemical constitution of drugs and their action on the organism, and will appeal as much to chemists as to the medical profession.

The Qualitative Analysis of Medicinal Preparations. Second edition. By H. C. FULLER. London: Chapman and Hall, Ltd.; New York: John Wiley and Sons, Inc. 1920. Pp. 191. 12*s.* 6*d.*

A KNOWLEDGE of the use to which a medicine is to be employed is obviously often a guide in arriving at its possible composition, and its price will often suggest what will probably not be present. Mr. Fuller rightly points out that most of the tests devised for detecting active ingredients have been worked out on pure substances and that little or no account is taken of the influence on the reaction of other substances present, for example, in a complex medicine. He has therefore devised a scheme of separation by which the different substances are obtained at particular stages of the analysis and their identity established by suitable tests. The first portion of the work describes the preliminary manipulation for the separation of the ingredients into large groups, followed by the separation into smaller groups and

Annotations.

"Ne quid nimis."

THE RESEARCH DEFENCE SOCIETY.

THE Research Defence Society was founded in 1908 with the object of enlightening the public on questions relating to animal experiment, and methods of medical research generally. The direct aim was the creation of an association which could rebut, on behalf of scientific workers, the attacks made upon physiological endeavour sometimes by individuals and sometimes by societies of apparently humane bent. It is recognised that, in most instances, the abuse is due to the kind heart of the critic as much as to his ignorance, but it has not been possible to take so urbane a view of certain persistent misrepresentations. Experiment upon animals has been successful in throwing light upon or actually combating many processes of disease, and it has been the task of the Society to distribute authoritative statements, written in language which could be appreciated readily by any intelligent lay reader, and disposing of the sinister rumours which have been prevalent for some time concerning the deeds and the personalities of working physiologists. The Society, since its inauguration, has obtained the active support of a large number of medical men, and also of many enlightened laymen, and success has encouraged it to further efforts, but closer contact with the general practitioner is very desirable. For while the medical profession is obviously in the best position to appreciate the ultimate merits of experimental work, and to realise how important it is that physiological and pathological research should be unfettered in its beneficent purposes, it is the general practitioner who can best bring this home to the public. Through the advocacy of the general practitioner a rapid extension of the work of the Research Defence Society might speedily result. While it is realised that difficulties stand in a medical man's way should he become an active propagandist, yet it is well known that many opportunities present themselves to medical men, during the course of their professional work, of influencing opinion in the right direction.

The Research Society welcomes all members of the medical profession as members or as associate members of the Society, or to associate themselves with the Society upon the following terms :—

Full membership: By subscribing to the Society 10s. per annum, receiving in return the published reports and pamphlets of the Society free of cost.

Associate membership: By subscribing to the Society 5s. per annum, and receiving in return such reports and pamphlets of the Society as are desired at cost price.

Association: By requesting the publications of the Society to be sent to them at cost price, or by requesting that there shall be sent to them, at cost price, such pamphlets as would be of particular use to them in propagating knowledge of methods used in medical research work.

A post-card will elicit further particulars from the Secretary, Research Defence Society, 11, Chandos-street, Cavendish-square, London, W. 1.

PROTEIN SENSITISATION AND BRONCHIAL ASTHMA.

AMONGST the many diseases which have been ascribed to anaphylaxis since Charles Richet's classical researches in 1902, bronchial or spasmodic asthma probably occupies the most important place. It is true that the various stages in the mechanism of sensitisation are still obscure and that we have had to fall back on ill-defined terms such as "indirect" or "secondary" anaphylaxis to bring spasmodic asthma into line with the true experimental anaphylaxis of animals. But the clinical picture of the disease, its frequent coincidence with drug hypersusceptibility, serum sickness, and the like, and, most important of all, its close resemblance to the signs and symptoms noted in anaphylaxis in animals, afford substantial evidence of a close relationship. As long ago as 1909 Auer and Lewis[1] showed that the lung of an anaphylactic guinea-pig presented changes resembling bronchial asthma in man, and since that date there has been a steady stream of research on this important subject, culminating in a long series of observations of a highly original character by Dr. I. Chandler Walker[2] and Dr. R. P. Wodehouse[3] in connexion with the Choate Research Grant in America. These researches were commenced in 1916, but the wide significance of them is only now beginning to be realised. Briefly stated, Chandler Walker has shown that if a foreign protein be inoculated into a superficial scarification of the skin in an asthmatic—and presumably sensitised—patient, an urticarial wheal may result at the site of inoculation within the brief space of half an hour. Not every foreign protein will act thus, and not every asthmatic patient is hypersensitive in this way. Some patients react to dried bacterial proteins, others to blood serums, others only to protein split products of hairs, feathers, wool, vegetables, &c. A positive reaction is regarded as an indication of abnormal protein sensitisation of the patient with that particular substance, or a split product of it. A large range of substances may be tested in one patient, and in a recent article Dr. J. F. Ward[4] reports cases in which as many as 80 and 90 different protein tests were made before a positive reaction was obtained. The issue of the *New York Medical Journal* containing this article is largely devoted to protein sensitisation and contains much interesting information.

A vast field of clinical research is thus being opened up and as usual a caveat is needed. In the first place it is clearly important that the cases investigated should be unmistakable cases of true spasmodic asthma, and that other possibilities, such as pulmonary tuberculosis or renal disease, should be ruled out. A case has recently come to our notice, for example, in which a so-called asthmatic patient, after many negative tests, was found to give a positive reaction to the protein of hen's feathers and advised accordingly, but within a few weeks tubercle bacilli appeared in the sputum and the whole aspect of the case was necessarily altered immediately. Such instances will doubtless become frequent unless every clinical and pathological means of investigation are first brought to bear upon the case. Again, a large series of controls in normal persons requires to be made as soon as possible, since it is not unlikely that we may all be found hypersensitive to some protein substance or other if only a sufficiently large series of tests be made. On the experimental side also the gaps in the chain of evidence must not be lost sight of. Protein sensitisation and its mechanism are but little understood, and in the case of asthma the relationship to anaphylaxis is at present partially inferential. It may not be difficult to visualise some of the steps, at any rate, in the mechanism of a protein reaction with wind-blown pollen or ingested food, but the intermediate stages of protein infection with material from a feather pillow enclosed in a stout bed tick and a frequently washed linen pillow case are not quite so obvious. The mechanism of protein sensitisation within the bodily tissues is also a matter needing careful thought and experimental research. Is it analogous to tuberculin sensitisation on the one hand, or to the Schick test for diphtheria, with its assumption of natural immunity, on the other? And, finally, is it a matter of physico-chemical, humoral or cellular disturbance, closely allied, as in true anaphylaxis, to shock?

These and cognate questions await an answer. Meanwhile it behoves us to proceed warily. The

THE LANCET.

LONDON: SATURDAY, DECEMBER 3, 1921.

The Sanctity of Medical Certificates.

AT the session of the General Medical Council, which has just been concluded, certain practitioners were summoned to appear on the charge of improper issue of medical certificates, and after the consideration of their case by the disciplinary body of the profession received a serious warning. The giving of medical certificates is now an onerous part of the practitioner's duty, and the work has been largely increased by the passage of the National Insurance Act with no commensurate increase of emolument. It might be well if the General Medical Council would consider the making of a representation upon this point to the Privy Council, or through the Privy Council to the Government; but it is absolutely necessary that the General Medical Council in carrying out its duties as a disciplinary body of the profession should insist that such certificates as are given by medical men should be given only with a full sense of responsibility.

When the new system of medical certification of incapacity of insured persons for work was introduced in 1915 the function of the general practitioner as certifier was brought under review, and it would now be well to inquire how far the innovation has been successful in meeting the difficulties of both parties. The complaints recently made by approved societies hardly refer to the difficulties which led to the establishment of the new system, being concerned rather with the few flagrant instances of unprofessional conduct. When such complaints are found after investigation by medical service sub-committees to be substantiated, it still remains to consider how far these lapses are due to mere slackness and want of appreciation of the importance of certification, and how far to the ignorance of the practitioner as to his obligations both moral and legal towards his patients and the insurance authorities. Certificates appear to be looked on by certain practitioners as matters of form incidental to ordinary practice, and two instances which came before the General Medical Council at the session just closed illustrated this fact. Medical certificates are most important documents. Those required by the new system of certification ensure certain benefits to the sick insured person legally entitled to them; they also safeguard the approved society endowed with certain statutory duties. But the certificate of a medical man is in most cases the main guarantee against fraud or illegal demands on insurance funds. A certificate is defined as "a written declaration of some fact," and to certify is defined as "to make known as certain." The form of certificate is so worded that it states certain "facts" and certain opinions. The first fact is that the certifier has "this day," or on a certain day, examined the patient. The second fact is that in the opinion of the certifier the insured person is incapable of work, and the third fact is that he is incapacitated by reason of "a specific disease or bodily or mental disablement." Of the first there can be no doubt, but in the second and third statements the fact is associated with the opinion of the certifier, acting to the best of his knowledge and belief. His signature is the guarantee of bona fides, which is shaken not so much by the correctness or otherwise of the opinions stated in the certificate as by the deception practised when certificates are given under circumstances which preclude proper consideration or render it impossible for the statement to be true. Although a uniform phrasing saves time, it is in one respect almost a pity that so much of the certificate is printed. Had the statement to be written out it would be perfectly clear what is the nature of the statement which the practitioner is making when he attaches his signature.

The medical certificate is the main evidence or guarantee on which sickness benefit is paid; it has been compared to a cheque payable on demand, but it is not the only evidence and societies are compelled by regulations to review such certificates and to regard them in the light of any other facts concerning the sick insured person within their knowledge. They may even refuse to acknowledge the certificate as a proper guarantee and decline to pay benefit, but they would be required in such a case to show cause for refusal, if the insured person exercises his right of appeal. Many a practitioner rightly regards it as a matter of pride for his certificates to be questioned, for the value of the certificate and the estimation of the facts and opinions it contains depend to some extent upon his professional reputation. In the ordinary course of administration, certificates are reviewed for various reasons and a routine method is adopted for selecting cases to be referred to the regional medical officers. The first reason appears to be the duration of illness; these officers were appointed to provide a further opinion in cases of prolonged incapacity. The second reason is vagueness of wording and the use of such phrases as debility or catarrh. Where the certificate is purposely vague, a precise description of the disabling condition must be furnished to the official referee. The third reason for referring cases is the receipt from a sick visitor of a report which, from the lay point of view, throws doubt on the insured person's incapacity, owing to something in his observed conduct or activities. Close coöperation with the regional medical officers will assist the practitioner in obtaining justice for his insured patients and in protecting himself from the importunate person who may readily make his life a burden. Certification is a many-sided obligation.

Epidemiology of Influenza.

THE preface to Dr. WARREN T. VAUGHAN's important epidemiological study[1] of influenza is dated Sept. 17th, 1920, and he was therefore not able to use the elaborate report on the great pandemic issued by our Ministry of Health 12 months ago. While the author may regret this circumstance, since it has deprived him of the opportunity of strengthening certain conclusions and modifying others, the reader will welcome a completely independent account of the same series of events from the Harvard Medical School. The preliminary sections of the monograph treat on familiar lines of the history of influenza. Prof. RAYMOND PEARL's study of the correlation between the explosiveness of an outbreak and the pre-epidemic general rate of mortality in cities is fully described. In English cities the standard death-rate was highly correlated with the death-rate of the first wave, but little correlated with the death-rate in the second and third cases. They commonly measure from 0·5 to 0·3 cm. in diameter. The deformity ranges from slight kinks or angulation of the tube caused by dragging or outside pressure to total obliteration. Dr. Andrews is of opinion that this duodenal deformity is a very constant feature of medical and surgical diseases of the upper abdomen, and that pouches and diverticula form a constant if small proportion of those deformities. Some of these defects are only apparent owing to outside pressure, spasticity, or temporary exudate round callous ulcers. Some are transient and relieved by medical treatment. A residue of permanent structural deformity is found and of this number a small minority have actual pouches which require operation.

ANTITETANUS IMMUNISATION.

IN certain parts of this country tetanus is so prevalent among horses that it is the custom for veterinary practitioners to inject a dose of antitetanic serum before performing any cutting operation upon a horse, and, in the case of an accidental wound which has come in contact with the ground, to inject serum as a matter of routine. In such districts it would be an immense gain to the owner and breeder if he could confer upon foals and young stock an early and lasting immunity against tetanus. The paper read on Nov. 15th[1] before the Pathological Section of the Royal Society of Medicine by Mr. J. B. Buxton, F.R.C.V.S., and Mr. A. T. Glenny, B.Sc., assumes, therefore, an aspect of practical importance. Five hundred horses tested by them gave no evidence of possessing any antitoxic immunity. An injection of tetanus toxin containing 20 test doses over-neutralised with antitoxin was administered thrice at intervals of three days. A month later the horse so immunised was found to tolerate a quantity of toxin exceeding 2000 guineapig-lethal doses and probably equal to several hundred minimum horse-lethal doses. Had these facts been available previous to the war, no doubt they would have been applied to the saving of the lives of many valuable horses. The duration of the immunity conferred remains to be accurately determined, but should the method prove, on further trial, to be a safe preventive against tetanus, it might be expedient so to immunise every horse in the kingdom. The collateral question will then arise whether the same method can be applied to prevent accidental tetanus in the human subject.

PROF. FRANKL IN DUBLIN: CURRENT GYNÆCOLOGICAL PROBLEMS.

THE Dublin School has long been distinguished for its broad outlook on diseases of women, and the recent visit of the distinguished Viennese professor of gynæcology, Dr. Oscar Frankl, in response to an invitation from the Royal Academy of Medicine in Dublin, was part of a lively interchange of thought with Continental medicine. Prof. Frankl delivered a series of lectures, one of which dealt with the interrelationship between menstruation and ovulation, a subject of great interest, upon which our knowledge is still far from perfect. He began by pointing out that the functions of the female genital glands can continue regularly and satisfactorily only if the balance between the different ductless glands is maintained. The disappearance or the hyperfunction of a gland immediately produces a disturbance in the physiological balance, which has been termed dyshormonia. Seitz has happily compared the effect to the constituent parts of an orchestra which are not in tune. Faulty playing on the part of one performer produces a discordant effect upon the whole. The cyclic changes in the uterus which accompany menstruation are produced by the effect of the internal secretion of the ovary, and this organ in its turn is maintained in a proper condition of function by the secretions of all the other ductless glands of the body. Frankl believes that the ovum and the corpus luteum are the most important hormone-producing tissues in the ovary, and that the onset of menstruation marks the death of the ovum. When the ovum lives and becomes embedded in the mucosa of the uterus then the corpus luteum persists, and menstruation does not take place. The result of exact histological study has demonstrated that the follicle ruptures about the fourteenth to the sixteenth day from the end of the last menstrual period, and that menstruation and ovulation do not coincide as was taught by Leopold and others. Thus it would appear that the corpus luteum prepares the uterine mucous membrane for the reception of the ovum, and that the involution or death of that body produces the hæmorrhage of the menstrual period. The apparent contradiction that the same secretion produces first hyperæmia of the endometrium, and that then its absence produces the menstrual bleeding, is explained by Frankl as follows. During the premenstrual stage the glands of the uterine mucous membrane are distended with secretion which contains a tryptic ferment, while by the swelling of the mucosa the mouths of the glands are more or less closed. When the corpus luteum begins to involute the hyperæmia subsides, the swelling diminishes, and the contents of the glands escape. The tryptic ferment then produces a more or less extensive digestion of the mucosa and consequent bleeding, and it is the presence of this tryptic ferment which accounts for the non-coagulability of the menstrual blood. It is interesting to note that Frankl does not believe in the presence of an interstitial ovarian gland in a sexually mature woman, and maintains that at present we have no proof of its existence or of its function.

In another lecture Prof. Frankl dealt with the method of treating cases of malignant disease by the action of X rays or radium, a subject which is attracting as much attention at Vienna as it is in Dublin. Such extravagant hopes have been excited in the minds of many by the reports of successes obtained by one or other of these methods that an impartial review of the results to be expected is of particular value. The chief defect of radium is its very limited area of action, which does not extend probably more than 4 c.cm. from the centre of the tube. Its effectiveness further decreases in ratio to the distance, and the peripheral portions of a tumour may therefore not only receive a dose which is insufficient to destroy the cancer cells, but even a dose which has the effect of acting as a stimulus to the cells and causing rapid proliferation and early metastasis. The ideal treatment is one which exposes all the cells within the radius of the rays to the same quantity and quality of rays. All the cells of the body are sensitive to the X rays or radium, and especially cancer cells and the specific cells of the ovary. It is therefore possible by the use of certain qualities and quantities of rays to destroy not only tumour cells, but also the follicles of the ovary without any harm to the surrounding tissues. The difficulty of the treatment lies in the fact that it is impossible to expose all the cells of a cancer mass of a certain thickness to the proper dose, and not to apply a dose which has the effect of only provoking stimulation and proliferation or of destroying the health-surrounding tissues. To produce such a result it is necessary to use the hardest rays obtainable. In an endeavour to obtain better results than the very unsatisfactory ones which accompany even the most radical operative procedures in the treatment of cancer of the neck of the uterus gynæcologists have perhaps expected too much from the use of X rays and radium. As Frankl points out, there is no excuse for abandoning the knife in favour of such treatment, but a combination of the two methods promises to give better results than either alone, and it is particularly important to subject cases operated upon to subsequent treatment with one or other of these methods. It is undoubtedly true that in a small percentage of cases ray treatment may render an inoperable case operable, or may even bring about its cure, a sufficient number of such place of the old-fashioned noisy rotating shafts and belts. To enforce the abolition of unnecessary din Prof. Spooner calls for an improvement in the existing laws. Public opinion has already led to some advance. We need submit no longer to the nerve-racking key-bugles of beanfeasters or the shrill whistling of commissionaires for taxis. But no public authority can yet prevent the screeching of a steam-saw in the vicinity of dwelling-houses. To those who suffer thus, only a civil action at law is open with all its costly delay. But progress under stress of economic pressure may prove more prompt than legal enactment. Prof. Spooner considers the advisability of fixing a limit of permissible noise, for which purpose a unit, or standard of noise would be necessary. It might be difficult to find such a standard, although in general it would be fair to regard as "noise" any sound in street or workshop which necessitated the raising of the conversational voice within a few yards of the source of the sound. To replace a test sound so variable as the human voice, a noise-producer of a certain definite intensity could be devised, the inaudibility of which by normal ears within the stated distance would constitute the limit of permissible sound. But physical details may safely be left to the ingenuity and resourcefulness of the scientific engineer, once he has been given clearly to understand that civilisation is no longer to connote noise.

The Phenomenon of d'Herelle.

In 1915 F. W. Twort[1] described the occurrence of spontaneous lysis of micrococci derived from calf vaccinia, and attributed the phenomenon to ferment action. The same phenomenon was described independently by d'Herelle in 1917, and the latter's persistent investigations and constant advocacy of an interesting explanation of the facts observed has brought the subject into great prominence throughout the world. Briefly, the facts elucidated by d'Herelle are these. If an emulsion of a stool from a case of dysentery be filtered through a Chamberland filter the clear bacteria-free fluid obtained is capable of dissolving *B. dysenteriæ* Shiga, in vitro. Such extracts differ in their activity, the less active ones only destroying a certain number of the organisms, whilst the more active ones procure the complete solution of a whole culture. A still more striking fact follows: such lysed cultures contain the active principle in large amounts, so that when a trace of the solution obtained in the first experiment is added to a second normal culture of Shiga's bacillus this also undergoes lysis, and a trace of this solution will reproduce the phenomenon in yet a third culture, and so on indefinitely. Only living bacilli undergo lysis; dead cultures are not affected. These, in the main, were the first facts elucidated and they remain undisputed. The lytic phenomenon is attributed by d'Herelle to the presence of a filter-passing, ultramicroscopic living virus, which is an obligatory parasite upon the bacterial body, and is capable of cultivation only in the presence of such organisms; it undergoes no increase in ordinary culture-media. Since these facts were made known, the subject has been much broadened and all sorts of subsidiary phenomena have been brought into prominence. It has been shown that the lytic substances may be found in other situations than the intestinal contents, and that even when coming from this source they are not specific—that is, substances lytic for Shiga bacilli may be found in persons not suffering from dysentery. It has also been shown by J. Dumas that similar substances may be obtained from earth and some waters, and by J. Bordet, also from leucocyte-containing peritoneal exudates. The interpretation of the phenomenon has been a matter of active discussion and three main explanations have been put forward. Firstly, the contagium-vivum theory of d'Herelle; secondly, the view of T. Kabeshima, who believes the lytic agent to be an enzyme, basing this opinion upon the fact that solutions maintain their activity for years, and also that the principle can be extracted by acetone; such an extract will initiate lysis, which can then be propagated in series. The third view is that supported by the authority of Bordet, who has sought an explanation on developmental grounds and believes that a new strain of bacteria is developed, under the conditions of the experiment, which is susceptible to autolysis, and that it is the presence of the autolytic products which causes a similar modification in subsequent generations of bacteria, thus enabling the phenomenon to be propagated; in short, that bacteria in undergoing lysis produce the environment conducive to the development of an autolytic strain. Bordet has produced the d'Herelle phenomenon by using extracts from the peritoneal fluid of a guinea-pig which has received an injection of micro-organisms. These different views have given rise to a good deal of contentious literature; much of this is difficult to sift as the experiments adduced are by no means conclusive and the discussion occasionally degenerates into a series of formal contradictions. It has also been shown that under the influence of the lysin many cultures divide into two types, one of which transmits the lytic principle—and is Bordet's autolytic strain—whilst the other is resistant to lysis and does not transmit the property. These strains differ from one another, and from the "normal" parent strain, in certain of their properties. There is apparently a process of selection, by which a small minority of resistant organisms are enabled to establish themselves as a true-breeding type in a culture in which they were previously swamped by a majority of the sensitive strain. These results appear similar to those of J. A. Arkwright, who by a different method of selection was able to split dysentery cultures into separate strains. As regards the phenomenon of lysis the most attractive explanation appears to be the conception of an unorganised lytic enzyme whose continued transmission may be regarded as an example of the autocatalysis; the freeing of the catalytic enzyme by the actual process of lysis, just as in the hydrolysis of an ester the acid set free serves to accelerate the reaction. The statement that the rate of the reaction increases as it proceeds falls in very well with this view. d'Herelle,[2] in the face of all criticism, has maintained his theory of a living bacteriophagium. In reviewing the work which has been done upon this subject we are impressed by its importance from many points of view. It has certainly brought to light a type of bacteriolysis quite different from that described by Pfeiffer, and is full of suggestion with regard to immunity and therapeutics. It has long been becoming evident to bacteriologists that the ideas current in the last decade, as to the fixity of the characters by which they identify and define species, must sooner or later go by the board, to give way to a much broader conception whose limits are the limits of physiological variation, within which the characters of any given organism may change. d'Herelle's work exemplifies the complexity of many of the processes occurring in connexion with bacteria, and whatever the final explanation of these phenomena may be, we are indebted to him for his consistent exposition of them and for the stimulus which his views have given to bacteriological research.

being the time necessary for an effective sensitisation. Their serum injected into a guinea-pig immediately caused a marked hypercoagulability in the blood of this animal and produced the same property in man. This property renders the serum applicable to every kind of hæmorrhage, including that due to various blood dyscrasiæ and as a preventive in surgical intervention in parts liable to bleed or in hæmophilic patients; it may be used in doses of 10–20 c.cm. subcutaneously. There are no special contra-indications, and serum disease is exceptional and never severe. In healthy subjects in whom the blood coagulability was previously estimated by MM. Dufour and Le Hello, it was found that this was markedly increased after injection; and they are furthermore of opinion that the factor of increased blood coagulability may enter into the explanation of some of the hitherto unexplained phenomena of shock. In conclusion, 11 cases are cited by the authors of hæmorrhage after abortion, from uterine and vesical cancer, at the menopause, in hæmophilia, melæna and hæmatemesis in which the injection of this serum was followed by marked and immediate benefit.

INTESTINAL OBSTRUCTION DUE TO MECKEL'S DIVERTICULUM.

Two cases of this unusual condition were reported in October. Surg.-Captain M. L. B. Rodd, R.N., details[1] a case of intestinal obstruction in a boy of 17 whose appendix had been removed six months before. A large intussusception, starting 2 inches from the ileo-cæcal junction, was found at the operation; and when this was unravelled a diverticulitis was found, about 18 inches higher up, and this also was intussuscepted. The diverticulum was removed, recovery being uninterrupted. Another case is mentioned in which the condition, diagnosed as appendicitis, proved at operation to be a diverticulitis.——Major Dean F. Winn, Medical Corps, U.S. Army, gives an account[2] of a still more curious example of this condition. A soldier of 19 was being operated upon for appendicitis on Nov. 9th, 1920, and it was found difficult to bring the inflamed appendix up into the wound owing to a dense peritoneal band which held down the ileum. With difficulty the band was traced upwards and was found attached to the blind end of a Meckel's diverticulum 8 inches long. As the patient now began to suffer from shock, the diverticulum was not removed. The patient subsequently refused further operation, though warned of his risk, and he was discharged to duty on Nov. 26th. He was readmitted at 3 A.M. on the next day, Nov. 27th, again suffering from intestinal obstruction, and at the second operation, that evening, a band of omentum was found attached to the tip and side of the diverticulum, incarcerating several loops of dusky and distended bowel. This time the diverticulum was removed. Convalescence was normal. Each of these authors quotes a paper in the *Annals of Surgery* for May, 1921, by Coley and Fortune, who had only been able to find in the literature since 1917 16 cases of intestinal obstruction by Meckel's diverticulum.

POST-GRADUATE COURSES ROUND BRISTOL.

THE committee in charge of post-graduate study in medicine in the University of Bristol, encouraged by the success achieved in courses of demonstrations held recently in several country centres, is proposing to extend its activities by arranging for similar courses in other towns in the south-west of England. In rural areas with cottage hospitals, University lecturers undertake all these demonstrations, a course consisting, as a rule, of six. For towns of larger size, with hospitals of 100 beds, the University offers several alternative plans: (1) To conduct a course similar to those arranged for smaller centres, in which all the demonstrations are given by the University "team"; (2) to undertake nothing but the organisation and the advertisement, the course itself being given by members of the local hospital staff; (3) to combine the two schemes by making the University team responsible for some demonstrations, the remainder of the course being undertaken by the local hospital staff. Prospective centres are invited to appoint a local secretary to whom, or to the director of post-graduate studies, each practitioner attending the course pays a fee of two guineas, to cover the cost of postage, advertisement, and travelling; should there be any balance, an honorarium will be handed to the lecturer. A list of subjects is offered to the group who select a series of six. In the courses already held one demonstration has been given per week, the subjects being the treatment of fractures, the uses and preparation of vaccines, and recent work in cardiac disease. To each of these two demonstrations have been devoted. For the courses which it is hoped may be held next spring, a much wider choice is offered, including various aspects of surgery, medicine, gynæcology, ophthalmology, and so on. A synopsis of each demonstration that is offered for selection is given, and the group is thus able to find what is most likely to satisfy its needs. The advantage of such courses to the country doctor, who finds it difficult to leave his practice for more than a day at a time, is obvious. It is to be hoped that this kind of work will be widely undertaken, not only in the south-west of England, but also throughout Britain by the appropriate universities. To this end inquiries as to procedure will be welcomed; they should be addressed to the Director of Post-graduate Studies, Department of Pathology, University of Bristol.

TREATMENT OF SCARLET FEVER WITH IMMUNE HUMAN SERUM.

TREATMENT of patients suffering from an acute infectious disease with the serum of convalescents has been widely used in the United States and in Germany, particularly in the cases of scarlet fever and measles, but has not to our knowledge been employed in this country. The present extensive epidemic of scarlet fever in London should afford plenty of opportunities of testing the value of this new method. In a recent paper read before the Chicago Society of Internal Medicine, Dr. G. H. Weaver,[1] of the Durand Hospital of the John McCormick Institute for Infectious Diseases, reports his observations on 54 cases of scarlet fever treated by convalescent serum. All the cases were severe, 38 being of the toxic type, 6 being characterised by septic complications, and 10 showing a combination of toxic symptoms and septic complications. Only two deaths occurred, one in the toxic and the other in the septic group. In neither case was any appreciable benefit derived from the serum. The blood was taken during the fourth or early in the fifth week of the disease, only those being chosen as donors who were free from any suspicion of tuberculosis, whose blood gave a negative Wassermann reaction, and who had had a typical attack of scarlet fever without complications; 200–300 c.cm. were taken from adults, and proportionately less from bigger children. After the serum had separated from the clot it was drawn off, mixed with serum from two or three other patients, and 0·3 per cent. of tricresol added. Cultures were then made from the mixture which, if sterile, was placed in small bottles of 30 c.cm. capacity and kept in a refrigerator till it was used. The serum was injected intramuscularly in doses of 60–90 c.cm., half the amount often being injected into each thigh. Intravenous injections were sometimes used, but did not present any advantages over the other route. If no obvious improvement occurred a second injection was given after 24 hours. Beneficial effects, however, following clinical group of cases loosely called spasmodic asthma probably contains many varieties. It resembles the unsorted post-bag, and we shall be greatly surprised if the whole group yields its long held secret to any one form of specific remedy. Rather we may look to protein sensitisation to remove from the amorphous collection the one group of cases only, leaving us with a large batch still undesignated. Where the interest is so great, clinical enthusiasm is apt to overrun experimental data. This nimbleness is not a vice, but it demands watchfulness.

EPIDEMIC HICCOUGH.

TOWARDS the end of 1919, first in Austria and then in Italy, the attention of medical observers was drawn to a singular affection of short duration characterised by obstinate and inveterate hiccough, which was reported on by Economo at Vienna, Michele and Pisani at Florence, Cardarelli and Pontano at Rome. A few months later the appearance of the same affection was noticed by Dufour at Paris and by Gautier in Switzerland. The question arose whether this epidemic hiccough was a separate disease or a larval and abortive form of some more serious condition such as epidemic encephalitis or influenza. Prof. Pontano, with Dr. Trenti, made some elaborate researches on four cases under their care who were free from physical signs of any other affection and, moreover, had negative Wassermann reactions.[1] They attempted to transmit the disease to twelve other subjects suffering from various chronic affections by injecting blood *in toto*, or filtered through Berkefeld N. candles, or solution of fresh extract, and of pharyngeal washings. All the inoculations gave negative results. They distinguish this form of epidemic hiccough from that which is merely an hysterical manifestation of gastralgia and consider that it is a toxinfective disease as shown by its pharyngitis, its febrile and general symptoms and its consecutive asthenia. They point out that epidemics of hiccough have occurred in the past and discuss their relation to epidemic encephalitis and influenza, a theory maintained with much vigour by Dufour, Lhermitte, Gautier, and others. They are inclined with all due reserve to insist that no such connexion exists, that epidemic hiccough is not a myoclonic form of either of these two diseases and, moreover, does not exhibit any close epidemiological or clinical relation with them. They base their opinion on the negative results of the inoculations made by them.

FOOD AND NUTRITION IN AUSTRALIA.

THE problem of food and nutrition is engaging considerable attention in Australia, and a pamphlet summarising the essentials has been written by Dr. C. E. Corlette, surgeon to the Sydney Hospital, at the invitation of the N.S.W. Board of Trade. An examination of the climatic factor is included in this summary. The same general principles as to salt, vitamin, and protein requirements apply everywhere, but in hotter climates the caloric requirements are less, and the main question was to determine the reduction on the average of 3300 cals. adopted by the Inter-Allied Food Commission. Basal caloric requirements have not yet been measured in Sydney, but they should lie below the 1680 cals. for northern U.S.A., and above the 1290 cals. for Rio de Janeiro, or even 1090 if the lowest determination be taken. Between these places there is thus a margin of 390–590 cals. Dr. Corlette has attempted to calculate the figure for N.S.W. indirectly from the heat loss by respiration. In New York respiratory heat loss amounted to 27·7 cals., in Sydney to 21·6, in Rio to 15·8 per cubic metre of respired air in winter; 15·6, 15·9, and 11·4 respectively in summer. At a respiratory rate of 16 cubic metres per day the respiratory heat loss is 368 at New York, 302 at Sydney, 222 at Rio for the whole year: 443, 345, 253 respectively in winter; 249, 254, 182 in summer. The annual difference between New York and Sydney is thus 66 cals. per day; but actually it is more since summer and winter are not of equal duration, the advantage being with Sydney, which has shorter winters. The main heat loss by the body is through the skin, and it has been determined that the respiratory loss is 11–12 per cent. of the total. The total difference will thus be eight to nine times as great—i.e., over 500 cals. The average caloric requirement for Australia will therefore be 2800. A preliminary investigation by Dr. H. S. H. Wardlaw from analyses of the actual food consumption of five women and four men workers in the laboratory—i.e., individuals performing light work—gave 2110 cals. for the men and 1977 cals. for the women per day. The protein consumption was 71·2 g. for the men and 58·9 g. for the women. These figures become 2321 for men and 2175 for women, with 78·3 and 64·8 for protein, if the usual allowance of 10 per cent. be allowed for loss by waste. They correspond fairly closely with the estimate of Dr. Corlette, remembering that these individuals were performing light rather than average work. Prof. H. G. Chapman (in another pamphlet) considers that most men in Australia perform hard work during the day, and advocates 5000 cals. for the food purchased so as to allow for waste, which often amounts to over 25 per cent. Even this allowance gives a much larger caloric requirement than the calculations by Corlette indicate. The allowance for women was estimated at 2500 cals. Australians are big meat eaters, though the consumption of meat has lessened since the war. The use of proteins to supply calories beyond the 80 g. daily requirement for maintenance and growth is wasteful, since great loss occurs during utilisation due to specific dynamic action. This action is illustrated by considering the case of a starving man burning from his own stores 100 cals.; a quantity of protein yielding 100 cals. does not suffice to replace the loss. The giving of food raises the metabolism, like poking a fire; combustion proceeds at a greater rate, and both food and stored-up fuel are burnt. The output is balanced by 140 cals. from protein, 114·5 from fat, or 106·4 from sugar. In other terms specific dynamic action causes a loss of 30·9 per 100 cals. from protein, 12·7 from fat, and 5·8 from sugar. Carbohydrate is thus the best fuel for the body. Muscular work makes no appreciable extra consumption of protein, and either carbohydrate or fat best supply the calories. Carbohydrate, if amply provided, also reduces the protein consumption.

DUODENAL DIVERTICULA.

IN a paper[1] read before the Section on General and Abdominal Surgery at the recent meeting of the American Medical Association, Dr. E. Wyllys Andrews, of Chicago, states that our knowledge of duodenal diverticula falls naturally into two periods. The first, or necropsy period, extends from 1710, when Chomel first described the condition, to 1910, during which it was regarded as a rare and interesting anatomical deformity, while in the second, or Roentgen ray period, from 1910 to 1917, clinical evidence pointed to those diverticula being important factors in the syndrome of gastro-duodenal ulcer. Dr. Andrews adds that to this period, or perhaps to a coming third period, belongs the evolution of the operative cure of the condition. Buschi, of Bologna, in 1911 compiled 54 examples of duodenal diverticula, including three of his own, with a list of 62 previous authors. Duodenal diverticula are acquired rather than congenital deformities, as they belong mostly to the later half of life. The importance of age in the ætiology is shown by the fact that the youngest patient in Linsmayer's series of 45 cases was 36. The diverticula are usually single and most frequently situated near the papilla of Vater. Their direction varies, being forward, backward, upward, or downward in different

---

[1] Il Policlinico, xxviii., Practical Section, August 29th, 1921.

[1] Journal of the American Medical Association, Oct. 22nd, 1921.

Dr. Kingdon's character, had expressed himself satisfied with it. The Council's solicitor, having briefly recapitulated the facts, read letters as to Dr. Kingdon's character in the interval from Dr. J. C. Johnston Acres, Dr. Louis C. Bean, Dr. P. R. Dodwell, and Dr. James Smyth. Dr. Kingdon expressed his regret, and gave an undertaking in regard to his future conduct in relation to certificates. The Council's solicitor did not desire to address the Council in reply. No member of the Council desired to put any question to Dr. Kingdon through the chair. The Council having deliberated on the case in camerâ, the PRESIDENT announced the judgment of the Council as follows:—

> I have to inform you that the Council has considered the evidence as to your conduct during the interval which you have tendered and has resolved: "That it does not see fit to direct the Registrar to erase your name from the Medical Register."

The Case of Nathaniel Stevenson.—The Council considered the case of Nathaniel Stevenson, registered as of The Phœnix, Rainham, Essex, M.B., C.M., 1893, U.Glasg., who had been summoned to appear before the Council on the following charge:—

> "That, being a registered medical practitioner, you abused your position by committing adultery and eloping with Mary McArtney, a married woman, you having been the medical attendant of the family, of which adultery you were found guilty by the decree of the Court of Session, Edinburgh, dated May 28th, 1921, in the case of George McArtney or Macartney *v.* Mrs. Mary Lugton or McArtney and Dr. Nathaniel Stevenson, in which you were the co-defender; and that in relation thereto you have been guilty of infamous conduct in a professional respect."

There was no complainant in this case. Dr. Stevenson was not present in answer to his notice, nor was he represented by counsel or solicitor. The Registrar having read the notice, in the absence of a complainant the solicitor placed the facts before the Council. He proved the service of the notice and read a certified copy interlocutor which he put in in the case of George McArtney or Macartney against Mrs. Mary Lugton or McArtney, in which Dr. Stevenson was co-defender, and an account of the proceedings at the Court of Session from the *Glasgow Herald*, dated May 30th, 1921, and certified copies of the notes of evidence given at the hearing, which he also put in. This closed his case.

The Council having deliberated on the case in camerâ, the PRESIDENT announced the judgment of the Council as follows:—

> I have to announce that the Council has considered the charge made against Nathaniel Stevenson, and that it has judged him to be guilty of infamous conduct in a professional respect, and has directed the Registrar to erase his name from the Medical Register.

The Case of Alexander McRobbie Donaldson.—The Council considered the case of Alexander McRobbie Donaldson, registered as of Inglewood, Briercliffe, Burnley, M.B., Ch.B. 1905, U.Aberd., who had been summoned to appear before the Council on a charge amended by assent of the Council to the following terms:—

> "That, being a registered medical practitioner, you, on March 24th, 1921, signed and gave to one Arthur Baldwin a certificate stating that you had that day examined the said Arthur Baldwin, Mrs. Arthur Baldwin, Mrs. Leaver, Harold Leaver, and Arthur Leaver, and found them in good health and sound mentally and bodily and likely to remain so, whereas you had in fact made no examination whatsoever of the said Arthur Baldwin, or Mrs. Arthur Baldwin, Mrs. Leaver, Harold Leaver, and Arthur Leaver, which certificate was untrue, misleading, and improper; and that in relation thereto you have been guilty of infamous conduct in a professional respect."

Dr. Donaldson attended in answer to his notice, accompanied by Mr. Alexander Neilson, K.C., instructed by Messrs. Hempson, solicitors.

There was no complainant in this case, but it was brought to the Council's notice by the Senior Medical Officer of the Australian Imperial Force. In the absence of a complainant, the Council's solicitor then proceeded to place the facts before the Council. He called Major Morris, A.I.F., as a witness, and examined him as to the truth of his declaration. Major Morris and a colleague, Dr. E. W. Evans, had examined Baldwin at Tilbury as he was about to embark for Australia and had dissuaded him on grounds of physical unfitness from proceeding with his journey. Major Morris was cross-examined by Mr. Neilson. The Council's solicitor did not desire to re-examine Major Morris, who answered questions put to him through the chair by members of the Council. The Council's solicitor next called Dr. Ernest W. Evans, Senior Medical Inspector of the Marine Department of the Board of Trade, and examined him as a witness. Dr. Evans was cross-examined by Mr. Neilson, re-examined by the Council's solicitor, and answered questions put to him through the chair by members of the Council. Mr. Stanley Hamilton Foss, assistant manager of the Orient Line, was also examined as a witness. This closed the case against Dr. Donaldson.

Mr. Neilson addressed the Council on behalf of Dr. Donaldson. He read letters from the Registrar to Dr. Donaldson, dated August 18th, 1921, and Dr. Donaldson's replies thereto, dated Sept. 8th and 9th and Oct. 13th, 1921. He called Dr. Donaldson and examined him as a witness on his own behalf. Dr. Donaldson was cross-examined by the Council's solicitor, and answered questions put to him from the chair, and by members of the Council through the chair. Mr. Neilson did not desire to re-examine Dr. Donaldson. Mr. Neilson read testimonials as to character from Dr. Herbert Edmundson, Burnley, enclosing a resolution passed by the Burnley branch of the British Medical Association; from Dr. Andrew MacGregor Sinclair, ex-Mayor of Burnley; from Mr. R. Allan Baxter, clerk to the Burnley Insurance Committee; from Mr. William Clitheroe, district superintendent of the London Mutual Assurance Society, Limited, Burnley Branch; and from Mr. John William Clegg, L.S.A., of Burnley, which he put in. This closed his case. The Council's solicitor did not desire to address the Council in reply. The Council then deliberated on the case in camerâ, and subsequently adjourned.

WEDNESDAY, NOV. 23RD.

After the Council had continued its deliberations in camerâ on the case of Alexander McRobbie Donaldson, the PRESIDENT announced the judgment of the Council as follows:—

> I have to inform you that the Council has given very careful consideration to the charge brought against you and to the evidence produced in support of it, and has found that the facts alleged against you, as indeed you yourself have acknowledged, have been proved to its satisfaction, and that the certificate in question was given, in your own words, in a "lax and careless" manner. The Council regards laxity in the giving of such a certificate as a very grave matter, and worthy of severe censure; it has resulted, as has been shown in this instance, in consequences injurious to the persons to whom the certificate is given, and to others. The Council, having regard to your previous good character and to the warning which you have received during the course of these proceedings, trusts that your conduct as touching certificates will in future be beyond reproach; and it has accordingly not seen fit to direct the Registrar to erase your name from the Register.

Dr. Donaldson thereupon gave an undertaking to the Council as to his future conduct in the giving of certificates.

The Case of Nariman Bejanji Kolsa-Walla.—The Council considered the case of Nariman Bejanji Kolsa-Walla, registered as c/o Grindlay and Co., 54, Parliament-street, S.W. 1, L.M.S.U. 1910, Bombay, D.P.H. R.C.P.S. Eng. 1914, who had been summoned to appear before the Council on the following charge:—

> "That, being a registered medical practitioner, you have sought to attract to yourself patients in the villages of Rainworth and Blidworth, Nottinghamshire: (1) by personal visits to and/or interviews with persons who were to your knowledge panel patients of Nowroji Merwanji Tarachand, a registered medical practitioner; (2) by offering to charge a lower fee for confinements than the charge made by the said Nowroji Merwanji Tarachand; and (3) by personal attendance at a meeting held at the Wesleyan Schools, Blidworth, when those present were asked to put their names on your panel list, and forms of notice to change

cases having been recorded to establish this fact beyond dispute. Seven of 42 cases of inoperable cancer of the cervix have been cured in Frankl's clinique, while he reports that 58·8 per cent. of cases subjected to ray treatment subsequent to operation have remained well after a period of five years. In the treatment of hæmorrhage from the uterus due to the presence of myomata or unconnected with obvious signs of disease the rays act upon the follicular elements in the ovary, and by destroying these bring about a cessation of the ovarian secretion and so produce amenorrhœa. Just as small doses may have a stimulating effect upon the cells of a malignant growth, so they may stimulate the follicular epithelium of the ovary, and it has been suggested therefore that they might be employed in the treatment of obstinate amenorrhœa.

Both these lectures are included in a very full report which appears in the *Dublin Journal of Medical Science* for November.

JUBILEE OF THE FINSEN INSTITUTE.

A FEW weeks ago the Finsen Institute in Copenhagen celebrated a double event—its 25-year jubilee, and the opening of an annexe for the light treatment of surgical tuberculosis. Some conception of the size and importance of this Institute can be gleaned from the following figures. The staff includes 22 doctors, 108 nurses, and 84 other employees; the annexe for surgical tuberculosis has cost three million kroner, accommodates 145 in-patients, and is equipped for the daily treatment of 150 patients. Niels Finsen's hope that light treatment could be extended to deep-seated disease, notably heart disease, was not realised in his life-time, but his successors have kept his aims in view, and in 1913 they began that treatment of surgical tuberculosis with carbon arc light which has now come into general use at the Institute.

PLAGUE AND SMALL MAMMALS.

PLAGUE was imported into coastal towns of South Africa many years ago, but as little or no manifestation of the disease was reported for some years, it was hoped that the infection had died out. Quite recently an entirely new series of outbreaks have been occurring inland and far remote from towns. In his interesting paper in our last issue, Dr. L. G. Haydon, assistant health officer for the Union of South Africa, set out clearly the peculiarities of these outbreaks—viz., (1) they were confined to a scattered rural population; (2) no "domestic" rats could be found in the farms; and (3) the time-intervals between the small groups of cases showed that they were not closely connected to each other. These new manifestations could not at first be brought into line with the ordinary epidemiology of plague, which requires flea-infested rats living in the same house with human beings; consequently it was necessary to look round for some other agent in disseminating the disease. After long and careful investigation into the fauna of the infected parts of the country it was discovered that two varieties of smaller mammals, which lived in numbers in the fields, were extensively infected with the disease—namely, the gerbille (*Tatera lobengulæ*) and the multimammate mouse (*Rattus coucha*), animals living in close contact with each other and the commonest of the animals captured for identification. The human cases of plague were confined to people who lived in the open and followed an agricultural or pastoral occupation: in one case a history was elicited of having taken meals sitting on the ground riddled with burrows of these animals.

Dr. Haydon's short communication is of great importance. It shows that the chain of infection to the human being is in reality the same in both town and country; in the latter case two small rodents, very similar in habit to the field-mouse, are the responsible agent for disseminating the virus; in the town, the "domestic" black and grey rat perform this function. Similar epidemics have been reported from other parts of the world. In the early part of this century there was an epizoötic of plague amongst field rodents in Essex followed by a few human cases. In India outbreaks have occasionally been reported amongst field-mice on the threshing floors around infected villages. Comparatively little is known about the extent and duration of these outbreaks amongst field-rats, but in the light of recent work done by Kunhardt and Chitre it is safe to say that provided climatic conditions are favourable for flea-breeding and the mean temperature does not remain for long below 50°F., the disease will be kept alive by the abortive epizoötic that occurs at the commencement of the colder weather. In these conditions the disease will spread like an ulcer, healing in the middle but always creeping further afield at the edges. When the non-spreading or quiescent period of the year (presumably the cold weather) approaches, active manifestation will remain in abeyance, but will commence again where it ceased as soon as favourable climatic conditions return. Dr. Haydon points out that any measures for getting rid of these small mammals are extremely difficult to carry out; the best results have, he says, been obtained with carbon bisulphide. We would point out that no measure yet designed for the extermination of rodents is anything like so satisfactory as the epizoötic of plague itself. Taking into account the scattered nature of the population, the right course would appear to be (1) to warn the people of the danger of sitting about on the ground, particularly if rat-burrows are plentiful; and (2) to push the ordinary inoculation against plague in order to save the lives of the human beings who, in spite of warning, expose themselves to the danger of infection in the course of their daily work. Whether or no the disease will die out amongst the small mammals of the countryside depends largely on climatic conditions of which our knowledge is very incomplete.

ANTIHÆMORRHAGIC SERUM.

IT is a characteristic peculiar to medical discoveries that they nearly always have their origin in some chance clinical observation. To this MM. Dufour and Le Hello owe the discovery of an antihæmorrhagic serum which they have named "Anthema" which they credit with a hypercoagulant property, particularly rapid and responding to the most urgent and serious requirements which are so constantly met with in medical and surgical practice. In a communication to the *Progrès Médical* of July 16th, 1921, they relate the case of a young woman admitted into the Broussais Hospital with purpura hæmorrhagica, epistaxis, and gingival and uterine hæmorrhages. The usual antihæmorrhagic remedies were applied without success. She had in particular several injections of antidiphtheritic horse serum which seemed without effect, when some days after the last injection the temperature rose suddenly to 40° C., and a generalised erythema made its appearance. At the same time the hæmorrhages ceased. Five days later they recurred and another injection of the serum was given, followed by fresh local reaction, urticarial eruption, and rise of temperature. At the same time, as in the first instance, the hæmorrhages stopped, but this time permanently. These facts led the authors to think that the voluntary production of these phenomena would be able to give rise to a well-defined humoral property—namely, hypercoagulability. Its realisation, however, seemed difficult. To obtain such an immediate effect as is necessary in hæmorrhages, it is not a question of the direct development in the patients of an anaphylactic state by excessive injection of serum, since it is well known that anaphylactic sensitisation requires a certain period of incubation for its production. But the patients can profit by the advantage that can be obtained from passive anaphylaxis by the injection of serum from a sensitised animal. Anthema is the serum of rabbits which have had, at intervals which have been regulated by experience, several very small successive intravenous injections of horse serum. The animals are bled 21 days after the first injection, he satisfies the Registrar of the General Medical Council regarding the other particulars set forth in Part II. of the Medical Act, 1886."

The report was adopted by the Council.

Revision of Standing Orders.

On the motion of Dr. NORMAN WALKER, chairman of the Business Committee, seconded by Sir ARTHUR CHANCE, it was agreed that the Executive Committee be requested to revise the standing orders and report to the Council at the May session.

Public Health Committee.

Sir JOHN MOORE, chairman of the Committee, presented this report. In pursuance of a resolution of the Committee agreed to at the May session, to which the Council accorded sanction, the Committee held a special meeting on Sept. 27th, 1921, the session extending over two days.

On Nov. 26th, 1920, the General Council authorised the Committee to consider and revise the existing resolutions and rules for Diplomas in Public Health originally adopted by the Council on June 1st, 1889, and amended and amplified from time to time, particularly on Dec. 1st, 1911, with a view to bringing the special course of instruction required of candidates for the diploma into harmony with the duties of a modern medical officer of health. In approaching their task the Committee had the advantage of perusing the reports of the visitors on recent examinations for the Diplomas in Public Health held by many licensing bodies, particularly the reports of the inspector appointed by the General Council, Dr. R. Bruce Low, on these examinations, and the general report by the inspector on the series of examinations—a most able document drawn up after an exhaustive inspection by a man of great experience in all matters relating to public health.

The result of their study of the various reports was that the Committee were of opinion that the time had come for a reconsideration of concessions granted to meet the exigencies of the war. They were convinced of the necessity for lengthening the curriculum and for lengthening the scope of study and raising the standard of examination generally. As an aid towards the attainment of these ends, the Committee hoped that the General Council would, in the impending revision of the curriculum for qualifying examinations in medicine, surgery, and midwifery under the Medical Act, 1886, lay stress on the necessity for developing the teaching of the preventive aspects of medicine in the course for those examinations.

The Committee noted that the existing examinations passed, on the whole, the ordeal of visitation and inspection satisfactorily, and it also recorded with gratification that the 21 licensing bodies which grant diplomas or degrees in "Sanitary Science, Public Health, or State Medicine" took in good part such criticisms as have been offered.

The inspector's reports on the various examinations were epitomised as follows:—

England and Wales.

1. *English Conjoint Board.*—"Judged by present standards the examination, in my opinion, is quite satisfactory."

2. *University of Oxford.*—"The examination exacts from the candidate a high standard of knowledge."

3. *University of Cambridge.*—"An efficient test of the competent knowledge of the candidate in regard of the duties of a Medical Officer of Health."

4. *University of Durham.*—"Candidates require to possess a distinctly high proficiency in all the branches of Public Health and Preventive Medicine."

5. *University of London.* M.D. (State Medicine) Examination.—"Candidates need to possess a very high standard of proficiency in all the subjects pertaining to Public Health and Preventive Medicine."

6. *Victoria University of Manchester.*—"The examination requires a good standard of knowledge from those who desire to obtain the Diploma in Public Health."

7. *University of Birmingham.*—"The examination affords an efficient test of the knowledge of the candidates."

8. *University of Liverpool.*—"The examination exacts a high standard of knowledge from the candidates in all branches of Preventive Medicine and Public Health."

9. *University of Leeds.*—"The examination requires from all successful candidates a high standard of knowledge of Public Health and Preventive Medicine."

10. *University of Sheffield.*—"The examination requires of the candidates a high proficiency of knowledge in Sanitary Science and Preventive Medicine."

11. *University of Bristol.*—"The examination affords a satisfactory test of the theoretical and practical knowledge of the candidates in Sanitary Science and Preventive Medicine according to present standards."

12. *University of Wales.*—"The examination requires from the candidates a high standard of knowledge in the various branches of Sanitary Science and Preventive Medicine."

Scotland.

13. *Scottish Conjoint Board.*—"The examination in its character and scope, and as carried out at Glasgow in my presence, in May, 1920, exacted from the candidates a distinctly high proficiency, scientific and practical, in the various branches of knowledge associated with Public Health and Preventive Medicine."

14. *University of Edinburgh.*—"The standard of the examination is above the average, and those who pass must show a high proficiency in all the branches of Public Health."

15. *University of Glasgow.*—"Candidates for the B.Sc. in Public Health of the University of Glasgow must attain to a high standard of knowledge in all branches of Public Health and Preventive Medicine before they can hope to be successful."

16. *University of Aberdeen.*—"The examination, as at present carried out, furnishes a satisfactory test of the competence of the candidates in Public Health and Preventive Medicine; it exacts a high standard of knowledge from those who submit themselves to the test."

17. *University of St. Andrews.*—(Report incomplete owing to clashing of dates with the examination at the University of Dublin on June 20th, 1921.)—"From the evidence with which I was supplied I have no reason to doubt that the examination was efficiently carried out."

Ireland.

18. *Conjoint Board in Ireland.*—"The tests applied to the candidates were prolonged and searching. They called for a high standard of knowledge in the various branches of Public Health and Preventive Medicine."

19. *University of Dublin.*—"The examination exacts from the candidates a high proficiency in the various branches of Public Health and Preventive Medicine."

20. *National University of Ireland.*—"The examination may be regarded as an efficient test of the proficiency of the candidates—it requires that the candidates shall possess a high standard of knowledge of the various subjects."

21. *Queen's University, Belfast.*—"The examination affords a satisfactory test of the knowledge of the candidates, who are required to show a high standard in all branches of Public Health and Preventive Medicine."

In addition to the inspector's reports and those of various members of the General Council acting as visitors, the Committee received valuable communications from individuals, whose scientific standing and wide experience of all that concerns public health and preventive medicine bespoke an attentive hearing and thankful acknowledgment on the part of the Committee. Many licensing bodies also, as well as members of the Committee and others, made suggestions as to the revision of the resolutions and rules for the Diploma in State Medicine. Finally, the Committee submitted for the consideration of the General Council a draft of revised rules for the Diploma in Sanitary Science, Public Health, or State Medicine.

The main rules suggested in this draft were briefly as follows:—

1. A period of not less than two years to elapse between attainment by a candidate of a registrable qualification in medicine, surgery, and midwifery and his admission to the final examination for a diploma in sanitary science, public health, or State medicine.

2. The curriculum for a degree or diploma in sanitary science, public health, or State medicine to extend over a period of not less than 12 calendar months subsequent to attainment of a registrable qualification.

3. Every candidate to produce evidence of having attended, during a period of not less than five months, at an institution approved by the licensing body granting the diploma, practical instruction in laboratory work in: (*a*) Bacteriology and Parasitology (including Entomology), especially in their relation to diseases of man, and to diseases of lower animals transmissible to man; (*b*) Chemistry and Physics in relation to Public Health. At least 180 hours must be devoted to course (*a*), including not less than

the injection occurred with great uniformity. Improvement in the general condition out of proportion to the change in the temperature curve was the most striking phenomenon. Two or three hours after the injection the temperature began to decline, the fever sometimes terminating by crisis.

RHODESIAN MAN.

EXPERTS have long differed as to whether the remains found in the Mousterian period and the various skeletons known as the Heidelberg man, the Piltdown man, and pithecanthropus are more or less in the direct line of descent of present-day man from the higher apes, or whether they count as offshoots from the human stem which did not mature. At a recent meeting of the Ulster Medical Society, which we briefly report, Prof. T. Walmsley emphasised the point of view that all these earlier types are more divergent among themselves than present-day human races and should rank as different species. Further light on the question may be expected when the precise systematic position has been determined of the skull unearthed by Mr. W. E. Barren last summer in a Rhodesian cave and now in the British Museum. In *Nature* for Nov. 17th Dr. A. S. Woodward, F.R.S., sets out the points in which this skull resembles and differs from those of other prehistoric findings. Its general appearance is strangely similar to that of the Neanderthal man, the large and heavy face being even more simian in appearance; the median longitudinal ridge shows an affinity to that found in pithecanthropus although much larger; the great flat maxillaries resemble those of the La Chapelle skull; the narial openings run down upon the face as in the gorilla, while the anterior nasal spine is typically human. The position of the foramen magnum gives reason to postulate an erect attitude, and the portion of the tibia found does not differ essentially from that of a tall and robust modern man. The fact that at first sight the dentition appears to be affected with caries makes this Rhodesian man very modern indeed. But these and many other points remain to be cleared up by discussion at the Anatomical Society of Great Britain and Ireland.

THE MEDICAL DIRECTORY.

THE Medical Directory for 1922, which has just reached us, is the seventy-eighth annual issue, and appears a week earlier than it did last year. The numerical summary of the medical profession on page 37 shows that the number of names in the London area is practically stationary, while there is an increase of 21 names in the Provincial section and much more considerable additions under the headings of Wales, Scotland, Ireland, Abroad, and the Services. The total number of names in the Directory is now 45,586, as against 44,926 last year—an increase of 660. A useful addition is the list of honorary secretaries of the statutory local medical and panel committees which appears on pages 33 to 35. The volume, though large, is handy and convenient, and the information it contains is not only accurate, but arranged with taste and a sense of proportion. The price of the Directory is 36*s*. net.

THE Thomas Vicary Lecture will be delivered at the Royal College of Surgeons of England next Thursday, Dec. 8th, by Sir Charles Ballance, who has taken as his subject A Glimpse into the History of the Surgery of the Brain.

A SOCIAL evening will be held at the Royal Society of Medicine on Wednesday, Dec. 7th, at 8 P.M., when the President of the Society and Lady Bland-Sutton will receive Fellows and their friends. At 9 P.M. Sir Berkeley Moynihan will deliver a short illustrated address on Medicine in Art.

GENERAL COUNCIL OF MEDICAL EDUCATION AND REGISTRATION.

TUESDAY, NOV. 22ND.

THE address delivered by the President was reported in last week's issue of THE LANCET. At its conclusion a vote of thanks to the President was carried by acclamation. The PRESIDENT then read a letter from Mr. Norman Bennett, formally tendering his resignation as a member of the Council.

Dental Education and Examination Committee.—Mr. Dolamore, Mr. Gilmour, and Mr. Guy were appointed additional members of the committee until the next election of the committee.

Dentists Act, 1921.—The Council proceeded to appoint three members, one from each of the English, Scottish, and Irish branches, to be members of the Dental Board of the United Kingdom; Mr. Waring, Sir James Hodsdon, and Sir Arthur Chance were appointed. On motions put from the chair, it was agreed (1) that the business of the Council arising out of the Dentists Act, 1921, be delegated to the Dental Executive Committee until the next session of the Council in May, 1922; (2) that Mr. Dolamore be appointed a member of the Executive Committee for Dental Business, and that the committee so constituted be the Dental Executive Committee under the Dentists Act, 1921.

Restoration of Names to the Medical Register.—The Council then deliberated on certain items of business in camerâ. Strangers having been readmitted, the PRESIDENT announced that the Registrar had been directed to restore to the Medical Register the names of Nariman Hormasji Clubwala and Thomas Stancy Sharpley.

Penal Cases.

The Council then proceeded to the consideration of penal cases.

The Case of Clement Thomas Cory Kingdon.—The Council considered the case, adjourned from May 24th, of Clement Thomas Cory Kingdon, registered as of 62, Falcon-road, Clapham Junction, S.W., M.B., C.M., 1893, M.D. 1905, U.Edin., who appeared before the Council on the following charge:—

"That, being a registered medical practitioner, you, on Feb. 7th, 1921, signed and gave to one W. McKernon, ex-member of the Australian Imperial Force, a certificate dated Feb. 5th, 1921, that the said W. McKernon was suffering from influenza, and was at present (i.e., on Feb. 5th, 1921) unable to travel, whereas you had neither seen nor examined the said W. McKernon on Feb. 5th, 1921, or at all before Feb. 7th, 1921; and that in relation thereto you have been guilty of *infamous conduct in a professional respect.*"

The complainants were the Australian Imperial Force, represented by Major E. W. Morris.

At the conclusion of the case the PRESIDENT announced the decision of the Council as follows:—

I have to inform you that the Council has found that the facts which were alleged against you in the notice of inquiry . . . . have been proved to its satisfaction, but that the Council has taken into consideration the evidence as to your previous good character and your assurance that the certificate was given without due care and thought. In order to give you an opportunity to rehabilitate your character and to prove to the Council that you realise the gravity of your offence, the Council has postponed judgment till the November session, when you will be required to attend and to produce evidence from your professional brethren regarding your conduct, and in particular in regard to your practice in the giving of certificates. Before that date you will be required to send to the Registrar of the Council the names of some of your professional brethren who may be willing, upon written application from the Registrar, to testify, by letter addressed to him for the use of the Council, as to your character and conduct in the interval. You will receive, in due course, a formal written intimation of what I have just announced to you, and the intimation will specify the dates to which I have referred.

Dr. Kingdon attended in answer to his notice. He was not accompanied by counsel or solicitor. The Australian Imperial Force, the complainant, was not represented, but Major Morris, its representative at the hearing in May, having seen the evidence as to were re-admissions, the number was reduced to 50 individuals; but the elimination of these duplicates did not, according to Dr. Barnes, make any material change in the percentage (2·7 per cent.) of patients with tuberculous consorts. That 2·7 per cent. of all married tuberculous patients should have tuberculous consorts is not surprising, as this percentage of the general population probably suffers from clinical tuberculosis. So far the case for conjugal tuberculosis is unconvincing. But the records of 229 consecutive widowed patients showed that 93, or 40 per cent., had lost their consorts by death from tuberculosis. As a control Dr. Barnes investigated the causes of death in 3400 married people under the age of 70, and he found that tuberculosis was the cause of death only in 12 per cent. According to this calculation, the percentage of persons widowed by tuberculosis is more than three times as great among sanatorium patients as among the general public. The objection may be raised that Dr. Barnes's comparison is misleading because, in all probability, most of his sanatorium patients were between the ages of 20 and 50. Yet he has compared their fate with that of married people up to the age of 70. Had he used as controls healthy widowed persons between the ages of 20 and 50, he would probably have found a higher tuberculous percentage than 12.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

MANCHESTER.

Dr. James Niven's annual report for 1920 is, as usual, a very interesting document. The death-rate from all causes is the lowest yet recorded: the low death-rate from tuberculosis also forms a record, while the marriage and birth-rates have risen. In the census figure for the population (730,551) the death-rate for the year works out to just under 14 per 1000 and the birth-rate 26·18. The (uncorrected) figure for the infant mortality rate is 97·08, the death-rate from pulmonary tuberculosis 1·1, and from other forms of tuberculosis 0·23. Dr. Niven pleads for a study of pneumonia. "Much work," he says, "has been done on its bacteriological study, but no real progress has yet been made towards elucidating its public health relations or the measures required for its reduction." Later in the report Dr. Niven points out that double occurrences of lobar pneumonia in a household are quite common, though frequently separated by considerable periods of time, and puts forward the suggestion that lobar pneumonia is, in a sense, infectious, though a third factor must be introduced to explain the vagaries of its infectivity.

On the question of venereal disease, Dr. Niven thinks we cannot yet say how much educational and clinical efforts have availed. In his view the question is largely one of prevention, and since he believes that the measures required to be taken by individuals are not difficult to apply, he considers it the duty of every person who incurs risk to take every possible means to avoid being the means of bringing destructive diseases to others. An early treatment centre was opened in December, 1919, and a second in September, 1920. Treatment is free and upon two conditions—viz., (1) that the exposure to infection has taken place within 12 hours; (2) that there are no signs of venereal disease. During 12½ months 3467 persons received treatment, 3218 coming from Manchester and Salford. The remainder were mostly from neighbouring districts, but 22 came from London and 12 from Liverpool. There is evidence that in 11 cases who exposed themselves to definite infection no disease developed. In the case of one centre the expenditure for 12½ months was £320, and of the other for four months £120. As regards the V.D. clinics, Dr. W. A. Young reports that far more males than females seek treatment. Among gonorrhœal cases the proportion of males to females is about 8 to 1. Dr. Young considers that little improvement in this respect can be expected until women are taught to regard all vaginal discharges as matters requiring special investigation. The number of cases ceasing to attend the clinics before completion of treatment is the most disappointing feature of the whole report, though good results were obtained at one clinic by sending out letters urging the patients to return to the centre. Dr. Young says: "The only remedy would appear to be in some form of notification of these cases with power to follow them up and compel them to continue treatment at approved centres or by approved medical practitioners until they comply with the accepted tests of cure." Provision for the intermediate treatment of gonorrhœa is inadequate, and patients resent the idea of going into the union infirmary at Crumpsall where alone accommodation, said to be excellent, has been made for pregnant women. At the end of 1920 there were 36 medical practitioners in Manchester qualified to receive salvarsan substitutes free of cost.

Dr. Niven states that, in spite of the assistance of the Panel Committee, notification of tuberculosis is still very late in many cases. He is puzzled by the considerable rise in the number of primary notifications of non-pulmonary tuberculosis, which accompanies a fall in the number of primary notifications of pulmonary tuberculosis. He does not think this is due to increased tuberculous infection in milk, and considers the possibility that there may be an increase in the number of tuberculous persons handling foodstuffs. The number of persons notified as suffering from pulmonary tuberculosis who were found to be handling foodstuffs in 1917, 1918, and 1919 was 66, 32, and 94 respectively. One of the conditions of notification of pulmonary tuberculosis was that the work of the notified consumptive was not to be interfered with. This has always been a weak spot in the regulations and ought to be amended.

Dr. D. P. Sutherland, the senior tuberculosis officer, deals with the failure to tackle the smoke nuisance, which is common to most mill districts. He attributes the "tolerance that is exhibited towards a death-dealing condition of this kind as in part the measure of Lancashire's preoccupation with its material progress. It tends towards decreased efficiency per unit, however, and in the larger view is very expensive." Dr. Niven has frequently referred to the importance of properly chosen and properly cooked food, and this report includes a note which has been issued to health visitors on vitamins. Manchester is now nearly up to date in scavenging arrangements, the relics of the evil past being represented by 217 midden-privies, 1322 pail closets, and 2182 wooden boxes for house refuse. We are surprised to learn that Manchester still tolerates such a state of things as that described in Dr. Niven's report on the nuisance from tips, several of which belong to the corporation and most of which were on fire in March, 1921. Manchester has apparently not gone in for destructors, and, we should think, would be well advised to consider the provision of one of the modern sorting plants which have given good results elsewhere. The shortage of houses was estimated at 17,727 in 1919. Dr. Niven says it is even greater now. In his next and last report Dr. Niven hopes to give a retrospect and a prospect as regards public health matters in Manchester.

SCHOOL MEDICAL SERVICE.

CAMBRIDGESHIRE.

There are 137 public elementary schools in this county, with a school roll of 10,822 children and an attendance of 10,229. Of these, 5356 underwent routine inspection, the number of children found to require treatment being 731, of which 328 received it. 3·7 per cent. of the routine cases suffered from enlarged tonsils and adenoids, 0·8 per cent. needing immediate operation. Breathing exercises are encouraged for those not requiring immediate operative treatment; printed instructions to this end are issued doctors to yourself were distributed, and that in relation thereto you have been guilty of infamous conduct in a professional respect."

The complainant was N. M. Tarachand, M.R.C.S., L.R.C.P., 1893. Dr. Kolsa-Walla attended in answer to his notice, accompanied by Mr. Norman Birkett, his counsel, instructed by Mr. E. B. Hibbert, his solicitor. Dr. Tarachand, the complainant, was accompanied by Mr. E. Huntsman, of Nottingham, his solicitor.

The Council's solicitor having read the notice, Mr. Huntsman proceeded to open the case for the complainant. After reading a letter from Dr. Kolsa-Walla to Dr. Tarachand, he called seven residents of the village of Blidworth and examined them as witnesses; these witnesses were in turn cross-examined by Mr. Birkett, and some were re-examined and questioned from the chair and by the legal assessor, also answering questions addressed through the chair by members of the Council.

Mr. Huntsman then called Mr. Nelson Frank Bayliss, clerk to the Nottinghamshire Insurance Committee, and examined him as a witness. He was also cross-examined by Mr. Birkett, and answered questions put to him, through the chair, by members of the Council. This closed the case for the complainant.

Mr. Birkett addressed the Council on behalf of Dr. Kolsa-Walla. He read a testimonial as to Dr. Kolsa-Walla's character from Mr. M. R. Saunders, L.R.C.P., of Hucknall, Nottingham, which he put in, together with other medical testimonials which he did not read. He also read and put in a statement from 77 panel patients who had transferred from Dr. Tarachand to Dr. Kolsa-Walla. The further consideration of the case was postponed, and the Council adjourned.

THURSDAY, NOV. 24TH.

The Council continued its consideration of the case of Nariman Bejanji Kolsa-Walla.

Dr. Kolsa-Walla attended, accompanied by Mr. Bertram Long, his counsel, instructed by Mr. E. B. Hibbert, his solicitor. Dr. Tarachand, the complainant, was accompanied by Mr. E. Huntsman, of Nottingham, his solicitor. Leave having been accorded by the Council, Mr. BAYLISS made a statement correcting certain statistics as to transfer of panel patients that he had given the previous day.

Mr. LONG then called Dr. Kolsa-Walla as a witness on his own behalf, and examined him as to the truth of the particulars set out in his statement of defence. Dr. Kolsa-Walla was cross-examined by Mr. Huntsman, and re-examined by Mr. Long. He answered questions put to him by the Legal Assessor and from the chair. Mr. Long next called Mr. Arthur Tyler, insurance agent, and four other witnesses, all of whom he examined as witnesses. They were then cross-examined in turn by Mr. Huntsman; several also answered questions put from the chair, by the Legal Assessor, and by members of the Council through the chair. This closed the case for Dr. Kolsa-Walla. Mr. HUNTSMAN addressed the Council in reply. This closed his case.

The Council having deliberated on the case in camerâ, the PRESIDENT announced as follows:—

> I have to inform you that the facts alleged against you in the notice of inquiry have been proved to the satisfaction of the Council; that the Council is of opinion that the practice of advertising and canvassing is contrary to the public interest and discreditable to the profession of medicine; that the Council takes a very grave view of such practices, but that, having regard to your comparative inexperience, it is prepared to give you an opportunity to prove that you are capable of more worthy conduct in the future, for which purpose it has postponed judgment till the November Session, 1922, when you will be required to attend and to produce evidence from your professional brethren regarding your conduct in the interval. Before that date you will be required to send to the Registrar of the Council the names of some of your professional brethren in the neighbourhood of your practice who may be willing, upon written application from the Registrar, to testify, by letter addressed to him for the use of the Council, as to your character and conduct during the next 12 months. You will receive, in due course, a formal written intimation of what I have just announced to you, and the intimation will specify the dates to which I have referred.

The Council then adjourned.

FRIDAY, NOV. 25TH.

The Council devoted this day to consideration of the reports of various committees.

Dental Education and Examination Committee.

This report was presented by Sir JAMES HODSDON, chairman of the committee, and dealt with three subjects: (*a*) colonial and foreign applications; (*b*) the dental curriculum; and (*c*) Dental Board of New South Wales. The revision of the curriculum was under consideration a few years ago, but the matter was postponed in view of the appointment of the departmental committee and the possible introduction of a new Dentists Bill. Now that the Bill had become the Dentists Act of 1921, and that the Council had the benefit of the advice of three members of the Dental Board, the recommendation was that it be referred to the Dental Education and Examination Committee to make suggestions for a revised curriculum in dentistry, and to report at the May session of the Council.

The report was adopted.

Union of South Africa and Empire of India.

The Executive Committee reported that, at its meeting on July 21st it received information that Part II. of the Medical Act, 1886, had been extended by an Order in Council to the Union of South Africa. The Committee having considered the curriculum of the University of South Africa, directed the Registrar as follows:—

> "That any person who holds the degrees of M.B., Ch.B., granted after examination in medicine, surgery, and midwifery by the University of South Africa, shall be entitled to be registered in the Colonial List of the Medical Register, provided he satisfies the Registrar of the General Medical Council regarding the other particulars set forth in Part II. of the Medical Act, 1886."

At its meeting on Nov. 21st the Executive Committee received and considered a further application for the recognition of its degrees from the University of Cape Town and instructed the Registrar as follows:—

> "That any person who holds the degrees of M.B., Ch.B., granted after examination in medicine, surgery, and midwifery by the University of Cape Town shall be entitled to be registered in the Colonial List of the Medical Register,"

with the same proviso as in the case of the University of South Africa. On the same date the Committee received a communication from University College, Johannesburg, formerly a constituent College of the University of South Africa, and the seat of its medical school, forwarding a copy of an Act of the Union creating the College a separate university under the title of the "University of the Witwatersrand, Johannesburg." The University of the Witwatersrand applied that the Council would grant to its degrees the same recognition as it did to those of the undivided University of South Africa. The Committee resolved:—

> "That the Registrar be directed to register in the Colonial List of the Medical Register any person who holds the degrees of M.B., B.Ch., of the University of the Witwatersrand, Johannesburg, granted after examination in medicine, surgery, and midwifery, provided he satisfies the Registrar of the General Medical Council regarding the other particulars set forth in Part II. of the Medical Act, 1886."

On the same date the Committee considered a communication from the University of Lucknow, to which the King George Medical College, together with its hospital and hostel had been transferred from the University of Allahabad, applying that the recognition hitherto accorded to the degrees of the University of Allahabad should now be accorded to those of the University of Lucknow. The Committee resolved:—

> "That the Registrar be directed to register in the Colonial List of the Medical Register any person who holds the degrees of M.B., B.S. of the University of Lucknow, provided

the fringe of this problem; there is work for at least three whole-time dentists among the 6–8 year group alone. Thirty cases of definite pulmonary tuberculosis and 58 suspected cases were reported, all of which received some form of treatment, 42 being sent to sanatoriums. The coöperation between the 25 infant welfare centres is strengthened by the employment of health visitors as school nurses; treatment of children 2–5 years of age might also be undertaken at these clinics.

SHREWSBURY.

Out of a school population of 5000 over 1000 were subjected to routine examination, and 1063 cases were treated at the school clinic, making altogether 4422 attendances. Of the 8-year-old group, 15 per cent. showed subnormal nutrition, compared with 6 per cent. of infants and 8 per cent. of leavers. No arrangements for providing school meals have yet been made, but, in spite of the high subnutrition no case of actual pulmonary tuberculosis is reported. 26·5 per cent. of infants were found to have dirty heads, whereas the intermediate group and the leavers showed only 8 per cent. and 4 per cent. respectively. This is contrary to the usual rule, infants generally showing a higher standard of cleanliness. A vigorous campaign against uncleanliness is being conducted. There is a comprehensive scheme of treatment, which is evidently taken advantage of to the full extent. The school medical officer, Dr. H. Gordon Smith, is also certifying factory surgeon for his district, and in this capacity is able to control to a certain extent the health of a large number of children after they have left school.

PRAGUE.

(FROM OUR OWN CORRESPONDENT.)

The Health Budget for 1922.

PARLIAMENT has approved the budget for 1922, amounting to 18 billion Czechoslovak crowns. The Ministry of Health and Physical Education has a budget of 149 millions, as compared with 18 millions in 1919, 46 millions in 1920, and 88 millions in 1921. The biggest item in the budget is 37 millions for the nationalisation of hospitals. This measure is due to the bad financial situation of these institutions owing to the war. Most of the hospitals have hitherto been in the hands of the district and provincial authorities, who had practically no resources, as the Austrian Government forbade them to collect local taxes. The second biggest item in the budget is 30 millions for maintenance of State institutions—hospitals, sanatoriums, preventoriums, and laboratories. Eleven millions are devoted to the fight against social diseases; this constitutes the biggest outlay for truly preventive work, the above-mentioned items being more curative than preventive. For special measures against epidemic diseases 12 millions are budgeted for, against 7 millions in 1921.

A Tuberculosis Sanatorium near Prague.

A large tuberculosis sanatorium has lately been completed at Prosecnice, near Prague; it was erected by the Central Federation of Sickness Insurance Associations, with money contributed by labour organisations. The sanatorium is well situated, with a good railway connexion; there will be 164 beds in the main building and over a hundred in the two wings, which are connected with the main block by open porticos. This establishment indicates an important advance in the antituberculosis campaign; hitherto Czecho-slovakia has only possessed two sanatoriums for adults with pulmonary tuberculosis, and institutional treatment, especially for the insured, was impossible. There are a number of pavilions for tuberculosis in district general hospitals, but these places are filled with advanced cases and cannot be counted as sanatoriums.

Masaryk Antituberculosis League.

The Masaryk Antituberculosis League is about to give a course on tuberculosis for physicians in the first half of December. The lectures will be given by a member of the Society for Research in Tuberculosis and will consist of a series of 54 theoretical lectures. In addition there will be practical exercises. The number of attending physicians is limited. The course is given chiefly for the benefit of physicians who want to be connected with the tuberculosis dispensaries which are being erected all over the country under the auspices of the Masaryk League. This is a second course of the kind this year, and it has been arranged because the number of those who decided to attend the first course exceeded by far the number which could be admitted.

Health Insurance for Civil Servants.

The Senate is discussing a Bill to insure State employees of all classes against sickness. No financial benefit would be provided during sickness, because at such times State employees receive either salary or pension. Medical benefit is also extended to the insured person's family; the patient is free to choose his doctor among those physicians who have contracted with the insurance authorities, and is entitled to stay in a hospital as long as it is necessary. Lying-in hospitals are included. The dependent mother, wife, and daughter of the insured would receive during the last six weeks of pregnancy not less than 400 crowns, and after childbirth 600 crowns and 100 a week premium for nursing the child, payable for a period not longer than 12 weeks. The Bill goes further than insurance for working men, in that it permits payment of transportation fees when patients have to leave home for treatment by a specialist. The Bill would not include employees in provincial or district services; the latter would then constitute the only salaried profession which is not yet included in some form of sickness insurance.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Tuberculosis in Belfast.

Dr. Andrew Trimble, chief tuberculosis officer of the city, has issued his report for the year 1920–21. It is a complete and, in most respects, a satisfactory document. The most important event of the year was the opening of the Municipal Hospital for Tuberculous Children at Graymount, consisting of a residence and grounds of about 15 acres; an open-air school for children in connexion with this institution is intended for "contacts." The children attending the school are provided with tram tokens for the journey to and from the school, and with two meals served during school hours. Open-air instruction is found to have a most beneficial effect upon the children. In the various tuberculosis institutes in the city 2121 examinations of new patients were conducted during the year. The new patients numbered 2234, including 113 transfers, compared with 2675, 2358, 3420, and 2977 in the four previous years. Pulmonary cases numbered 935, of whom 446 were males and 489 females. There were 119 glandular cases (44 male and 75 female); osseous cases numbered 82 (33 male and 49 female); and abdominal cases 28 (15 male and 13 female). There remained 22 other forms of tuberculosis, of whom 6 were male and 16 female. The preponderance of females is in accord with the experience of former years, and probably finds its explanation, in whole or in part, in the conditions of female employment. 1579 patients received treatment at the Institute, 3945 received domiciliary treatment, and 250 received sanatorium treatment. The total number of deaths was 978, of whom 762 died from pulmonary tuberculosis. This is a reduction of 91 deaths as compared with the previous year, and represents a

150 hours of practical laboratory work. At least 90 hours must be devoted to course (*b*), including not less than 70 hours of practical laboratory work.

4. Every candidate to produce evidence of having received, during not less than 100 hours, at an institution or from teachers approved by the licensing body granting the diploma, instruction in the following subjects: (1) Principles of public health and sanitation; (2) epidemiology; (3) sanitary law and administration; (4) sanitary construction and planning; (5) vital statistics; (6) meteorology and climatology.

5. Every candidate to produce evidence that he has attended for three months on the practice of a recognised hospital for infectious diseases, and received instruction in the methods of administration. At least 30 attendances in not less than two days in each week shall be required, and clinical records of not fewer than six cases observed in the wards.

6. Every candidate to produce evidence of a period of not less than six months, spent in acquiring practical knowledge of the duties, routine and special, of public health administration under the supervision of a medical officer of health, who shall certify that the candidate has received, during not less than three hours of each of 60 working days, practical instruction in these duties, including those relating to: (*a*) Maternity and child welfare service; (*b*) health service for children of school age; (*c*) venereal diseases service; (*d*) tuberculosis service; (*e*) industrial hygiene; (*f*) inspection and control of food, including meat and milk.

7. The examination for the diploma or degree to be divided into two parts, Part I. and Part II., each of which shall extend over not less than two days, and shall be conducted by examiners specially qualified. A candidate must pass in all the subjects of Part I. before being admitted to examination for Part II., and must pass in all specified subjects in either Part I. and Part II. at the same time.

8. The examination for Part I. to be practical, written, and oral, and shall include the following subjects: Bacteriology and parasitology (including entomology); and chemistry and physics in relation to public health.

9. The examination for Part II. to include the following subjects: Hygiene and sanitation; epidemiology and infectious diseases; sanitary law and vital statistics; public health administration.

The examination to be written and oral, and to include practical examinations in infectious diseases; meat inspection; inspection of premises, dwellings, workshops, schools, &c. Candidates may not be admitted to examination for Part II. until after they have completed the prescribed courses of instruction, and until after the lapse of not less than two years from the date of his obtaining a registrable qualification in medicine, surgery, and midwifery.

The report was received and entered on the minutes.

(*To be continued.*)

TUBERCULOSIS.

RECENT AMERICAN WORK.

Comparative Susceptibility of Men to Tuberculosis in New York.

IN the *Bulletin of the New York Tuberculosis Association* for September–October, 1921, attention is drawn to the remarkably high death-rate from tuberculosis among males, as compared with females. Since 1910 there have been 67,748 deaths from tuberculosis among males of all ages, and only 31,148 among females. The proportion is thus 64 to 36. As the population of New York includes practically equal numbers of males and females, these figures can be taken as a true index to the comparative death-rates for the two. In both sexes the death-rate shows an almost identical decline since 1910; it is 44 per cent. among males and 45 per cent. among females. As this decline has continued during the first months of 1921, it is calculated that in the past 11 years the death-rate from tuberculosis in both sexes in New York has been halved. The remarkable sex difference in the death-rate is correlated with the overwork and unhygienic conditions from which males suffer outside the home. Pertinent to this matter is the fact that while in 1920 alone 146,054 visits were paid by nurses in the homes of patients, not one such visit was paid in the workshops employing men.

Re-infection in Tuberculosis.

It is doubtful whether much advance has been made towards the solution of the tangled problem of re-infection by a long paper on this subject by Dr. Edward R. Baldwin and Dr. Leroy U. Gardner in the *American Review of Tuberculosis* for August, 1921. But their experimental investigations and comprehensive review of the literature of the subject should serve a useful purpose in charting the many pitfalls lying in wait for the unwary. To decide whether and to what extent primary infection confers immunity to a second infection from without, they inoculated guinea-pigs by the inhalation of tubercle bacilli of the human type and of low virulence. The first step was to produce, if possible, a completely arrested tuberculosis before re-infection was attempted. They made use of the culture isolated by Trudeau as early as 1891, and subsequently used extensively in the U.S.A. in experimental tuberculosis. They found that re-infection is quite feasible when relatively large doses of tubercle bacilli are given by inhalation, but the second infection did not form the caseated tubercles with the regularity seen in the primary tuberculosis. There was, instead, a localised inflammatory reaction with, as a rule, a moderate degree of proliferation. The tracheo-bronchial glands suffered no further disease in the mild re-infections; in short, an abortive form of the disease was provoked, and the exceptional cases not conforming to this rule could be explained either on the assumption of over-dosage or of absence of primary infection. In the second section of their work the authors attempt to apply clinical and epidemiological observations to the solution of the question: What proportion of old tuberculous foci is responsible for the clinical disease of adults? Their review shows that, according to different authorities, from 20 to 80 per cent. of clinical tuberculosis after the fifteenth year is derived directly from infection in childhood. The difference between 20 and 80 per cent. is rather wide.

Back to the Pulmonary Apices.

Of late years radiologists have been so engrossed by hilus tuberculosis that the apices of the lungs have suffered comparative neglect except by old-fashioned clinicians. A swing of the pendulum in this matter is to be found in a paper by Dr. James G. van Zwaluwenburg and Dr. G. P. Grabfield in the *American Review of Tuberculosis* for June, 1921. In a long series of cases they have paid special attention to a rather dense linear shadow, lying just beneath the second rib and over the apex of the lung, as seen in stereograms of the chest taken in the postero-anterior position. By imperceptible gradations these shadows merge into the well-known shadows of apical tuberculosis till it is impossible to distinguish the pleural from the pulmonary opacities. This study has led to the conclusion that the chronological order of this form of disease is: the lymphatics of the neck—the pleuræ—the apex of the lung. The phenomenon of pleurisy with effusion can be explained on the assumption that a serous exudate from an apical lesion gravitates to the lower thorax, spreading infection there. The suggestion is also made that the above route of infection is not necessarily the rule, and the prevailing distribution of the disease in children seems to point to some other route. In this connexion the guess may be ventured that the lymphatic drainage in the adult differs fundamentally from that in the child. Certainly radiologists agree that the picture of chronic pulmonary tuberculosis in the adult is very different from that in the child.

Conjugal Tuberculosis.

In a paper in the October number of the *American Review of Tuberculosis* Dr. Harry Lee Barnes discusses the possibility of tuberculous infection between husband and wife; incidentally and accidentally he shows how dangerous it may be to draw conclusions with regard to this much debated subject. His paper is based on the records of 5608 consecutive cases of tuberculosis admitted to the Rhode Island State Sanatorium. Of the 2262 married persons, only 62 of them stated that their consorts suffered from pulmonary tuberculosis. As 12 of these cases ference being recommended. After operation the re-education of muscles should be patiently carried out, taking care that the stronger muscles are kept in abeyance whilst the tone in the weaker muscles is being developed. For example, we often see inversion of the foot from an external popliteal nerve lesion, due to the over-action of the tibialis anticus. This would be avoided if the weaker peronei had been concentrated upon; a possible transplantation of the tibialis anticus, to correct inversion, would be unnecessary. This neglect of the weaker muscles is seen equally in recovery after musculo-spiral nerve lesions, where you get radial deviation on dorsi-flexing the wrist. *This can and should be avoided. In splinting* a hand or foot when paresis is present in the extensor group, full dorsi-flexion should not be resorted to. The extensor group will thus be able to work in the inner range if and when voluntary power returns, and a spasm in the antergic or flexor group will be avoided.

Some such scheme of coördination between schools, centre and orthopædic hospital, would help the work and objects of the Central Committee, and might form a basis for a national orthopædic scheme.

I am, Sir, yours faithfully,

M. Dockrell.

THE QUESTION OF SELF-DISINFECTION.

To the Editor of The Lancet.

Sir,—We, the undersigned, physicians and surgeons, medical officers of health, and officers in medical charge of venereal disease clinics, having reviewed the whole subject, have not formed our opinion on the question of self-disinfection without careful consideration. In addition to practical experience the following points are convincing:—

1. Such evidence as has been adduced in favour of this policy is founded on the results obtained in the Navy and Army among men, under discipline, who were carefully and in many cases individually instructed by certain enthusiastic and competent officers. When tried by other keen medical officers with men under discipline the method failed. Even had it been successful, to teach and instruct the civilian population in as detailed a manner is obviously impossible. *Careful individual and collective detailed instruction is given* to the troops of the British Armies of Occupation in Germany and at Constantinople. Materials and packets for self-disinfection are available, yet, in the Army of the Black Sea, the rate of infection was 213·73 per 1000 for 1920 and 238·94 per 1000 men for January to June, 1921 (House of Commons, Nov. 3rd, 1921) and in the Army of the Rhine the figures are 188·62 per 1000 men for 1920, and 148·90 per 1000 for January to June, 1921 (House of Commons, Nov. 3rd, 1921).

2. Unless disinfection is extremely carefully carried out it would fail to effect its purpose. In the largest clinic in London between July and September of this year, out of 375 men presenting themselves for treatment 101 had used some form of chemical disinfection, chiefly permanganate of potash, within a very short time of running the risk; and *from September up to date, of 201 new cases 47 had used permanganate of potash, the majority of them within 5, 10, 15, or 20 minutes after exposure to infection.*

3. Self-disinfection has been extensively carried out in Germany during the last six years, and great stress, during an intensive campaign, has been laid on the virtue of prophylaxis and self-disinfection. The German delegates at the Red Cross Congress at Copenhagen last May stated that in their opinion there was no evidence of diminution in the number of cases of venereal disease, and no sign of any fall in its incidence. Dr. Pinkus stated that, in Berlin alone, he *estimated that there were 25,000 fresh cases of infection each year.*

4. It is likely to lead to disease in large numbers of young persons. In Dresden, where the system of prophylaxis by self-disinfection has been actively pressed by poster, handbill, and address, it was found that the number of boys between 14 and 18 coming up for treatment at one clinic had increased during one year from 14 to 101, and of girls between the same ages from 60 to 116. In the first three months of 1921 the number of boys was 33 and of girls 61.

5. The first risk may be as fatal in causing disease as the *fiftieth, and a boy of 15 is just as capable of taking infection* and conveying the disease as a man of 50. Therefore, to carry out this policy effectually, it would be necessary to instruct every boy on reaching the ages of 14 or 15, and see that he is provided with disinfecting materials.

6. The argument in favour of self-disinfection is that it can be carried out without any delay. To fulfil this condition *it would be necessary for the disinfectants to be carried on the person.* This would be an ever present and continuing incitement to illicit intercourse, and would tend to lead to an increase in the number of risks incurred.

7. It is very nearly impossible for women satisfactorily *to disinfect themselves. This is shown by the conditions* existing in Constantinople, where instruction in the methods of self-disinfection has for some time past been given by medical men to all prostitutes at the examination centres. In spite of this, however, the number of infected women in this group works out at 560 out of 2000 each month.

8. Notwithstanding any warning given, a certain number *of individuals, in whom the diseases may have developed,* will persist in using the disinfectant materials as a means of treatment. By so delaying the use of true remedial measures, they will prolong the period of infectivity to others, and of treatment necessary for cure for themselves. This is within the experience of a number of the signatories.

We are, therefore, of opinion that the policy of promiscuous propaganda as to the security conferred by personal self-disinfection among the civilian population is likely not only to fail in its object in decreasing the amount of venereal disease, but also may actually lead to an increase in the gross number of cases.

We are, Sir, yours faithfully,

RENAL EFFICIENCY TESTS.

To the Editor of The Lancet.

Sir,—I was reported in your issue of Nov. 26th as saying at a recent meeting of the Bristol Medico-Chirurgical Society that there was a "close parallelism between the curve of fluid outflow . . . . and the output of urea." The charts shown were in illustration of the established fact that the specific gravity of the to teachers for systematic use in schools, and also to parents when desirable. During the year 374 cases of impetigo were reported (100 more than the previous year), and these cases, as also 26 cases of scabies, were treated in their homes, being kept under observation the while by school nurses. 5947 home visits were paid by the nurses, mainly for the purpose of "following up" and inquiring into infectious disease. Arrangements for the treatment of defective vision have been made with Dr. J. C. W. Graham and a travelling ophthalmic clinic will be held by Dr. J. H. Gellatly, assistant school medical officer. A motor-car carrying equipment is also provided for dental treatment.

The number of children dentally inspected was 10,372 (16·5 per cent. more than last year), and the number treated was 2467 (1 per cent. more than last year). It is satisfactory that the number of teeth extracted (4890) shows a decrease of 5·8 per cent., while 1088 teeth were filled, an increase of 13·8 per cent. over last year's figure. Dr. Frank Robinson observes that extraction is necessarily more frequent in a rural scheme of dentistry owing to the inability of the dentist to pay the number of visits required for fillings. This would seem somewhat hard on the country child. The proportion of refusals of treatment decreased from 40 per cent. in 1919 to 34·2 per cent.; it is interesting to note that this reduction was recorded among the re-inspected children, particularly among those for whom treatment had been previously refused. The school nurses paid 1453 home visits in connexion with the dental work.

The question of dealing adequately with defective children is being taken in hand. Special arrangements have been made for several of these cases, but further accommodation is required, and the suggestion that adjoining education authorities should combine in this matter may be fruitful.

Out of a total of 137 schools 109 schools were closed for infectious disease, 57 for measles, 17 for whooping-cough, 9 for scarlet fever, 5 for diphtheria, 19 for influenza and epidemic catarrh, 1 for chicken-pox, and 1 for mumps. These figures seem very high.

CHESHIRE.

Of an average school attendance of 55,123, the total number of individual children examined in the county was 20,396, including 3149 special cases. 3·6 per cent. were referred for treatment for uncleanliness. There were 535 cases of enlarged tonsils and adenoids, 341 of which suffered from enlarged tonsils alone, and 219 from adenoid growths. Dr. Meredith Young, commenting on two cases of "aprosexia" brought to his notice during the year, refers to the immediate and striking improvement in mentality which followed within a month of the removal of adenoid tissue. 845 cases of dental disease were treated by the school dentist, whose appointment has been amply justified, and there is evidently plenty of work for at least one other dentist in the county. 1440 children were referred for detailed examination by the school oculists, 451 prescriptions for spectacles being given. Special leaflets on myopia and squint, adapted from those in use in the county of Durham, were circulated among parents. These leaflets serve to educate parents who, as a rule, are lamentably ignorant of ocular hygiene. The appointment of two school oculists has facilitated the treatment of a much larger number of children than it was possible to have treated in former years. Dr. W. J. McIvor finds enlargement of the thyroid gland common in both girls and boys at puberty; he also reports many cases of hypo-thyroidism. No exact figures are given, but the condition is said to be accompanied by defective nutrition, anæmia, and ichthyosis. Dr. Young notes that the condition of enlarged thyroid is accompanied by moist hands, and is often associated with a history of night sweats and disturbed sleep.

The number of feeble-minded children attending public elementary schools is reported as 113, 16 attend certified schools, and 26 are out of school altogether. Dr. W. Stacey made an intensive examination of 108 cases suspected of mental defect, and found 64 of these fit to attend the ordinary elementary school with a little special attention. This information was given to the head teacher and a scheme for the education of these children was outlined. Of the 108 only 29 were definitely defective. 20,047 free dinners were supplied during the year, 740 being given out at the minimum charge of 1s. a week per family. In February, 1921, distress became acute in certain districts and new feeding centres had to be opened. Dr. Young has found that, in the case of infectious disease, teachers are not so anxious as they used to be to make out a case for school closure, and they have coöperated loyally in helping to prevent the spread of disease. Very much can be done in this direction by intelligent teachers. Dr. Young reports that the work of medical inspection has now returned to pre-war conditions. He suggests, however, that the work itself would be much more interesting if the school doctors could have a rest from routine inspection and employ their time on some specialised problem.

EAST SUSSEX.

The County Council of East Sussex has 37,833 children aged from 5–16, of whom 23,271 are on school registers and 15,069 were examined, 11,141 undergoing routine inspection. 136 suffered from malnutrition, 606 from nose and throat troubles, 133 from defective hearing, and 93 from ear disease. Altogether, apart from those with defective foot-gear or suffering from uncleanliness, 1760 children were referred for treatment, and 1329 required further observation. Dental treatment has begun, but it is still insufficient. There are also beginnings of treatment for ophthalmic and other cases. There is no preventive treatment so far for physically defective or weakly children. Provision of classes for dull and backward children is also unsatisfied. The nursing is generally done by district nurses, but 17 schools were unprovided in this respect. There were 80 school closures for infectious disease, including whooping cough 16, mumps 7, chicken-pox 6, influenza 2; as these were mostly rural schools closure may have been unavoidable. Dr. A. G. R. Foulerton reports that arrangements for 1921 include the prospect of more clinics throughout the county. The appointment of extra medical help will relieve the present pressure of work and give opportunity for further development.

PERTHSHIRE.

The education authority's scheme for medical inspection and treatment has been approved by the Scottish Board of Health with certain reductions—e.g., £50 for a second set of instruments for the dental clinic, £135 for fitting up a county clinic. The cost of clerical work and a heavy stationery outlay was criticised by the Board, but it is understood that the first item includes the cost of assistance at dental and medical clinics, while all office sundries are included under the heading of stationery. Plans and estimates for a clinic at the Old Infirmary Buildings are shortly to be submitted.

WARWICKSHIRE.

This excellent report is made cumbersome by valueless tables printed on foolscap. There are in this county 310 schools with 37,000 children; many of the schools are overcrowded. One-third of the 15,898 children examined were referred for treatment. Only 13 per cent. of the school population had unclean heads, but 5 per cent. were excluded for impetigo. There is now an extra minor ailment centre, making seven in all, and during the year 2525 received treatment here. The comprehensive scheme for treatment in the county as a whole is now in full swing. This is the first complete year of dental treatment, which is carried out by means of a motor-car with portable dental equipment. Dr. A. Hamilton Wood remarks that one man can only touch

Obituary.

PETER THOMPSON, M.D., CH.B. MANCH.,

PROFESSOR OF ANATOMY AT THE UNIVERSITY OF BIRMINGHAM.

THE death of Peter Thompson, which occurred at Penmaenmawr on Nov. 16th, after a long illness, causes a gap in the ranks of British anatomists which will not easily be filled. The only son of the late Mr. Peter Thompson, of Earlestown, Lancashire, he was born in 1871 and was educated at Upholland Grammar School. Thence he proceeded to Owens College (which afterwards became the Victoria University of Manchester), and after a distinguished career as a student he graduated M.B., Ch.B., with second-class honours in 1894, and in 1899 took the M.D. as a gold medallist. After holding the appointments of senior demonstrator of anatomy in Owens College and lecturer in anatomy in Victoria University, Thompson came to London and was appointed lecturer on anatomy at Middlesex Hospital. From 1901 to 1904 he was hon. secretary of the Anatomical Society of Great Britain and Ireland, and from 1905 to 1909 professor of anatomy and Dean of the Faculty of Medicine at King's College. He was then elected to the chair of anatomy at Birmingham, where he had been Dean of the Faculty of Medicine since 1912.

Thompson was always an enthusiastic anatomist, showing his wide view of the subject even in his student days. Trained under the late Prof. Young of Manchester, his work tended at first in the direction of comparative anatomy, with a view to the light thrown by this on human structure, and he came prominently into the notice of the anatomical world by his well-known work on "The Myology of the Pelvic Floor"; this was followed by papers on variants of the same subject, and also on other comparative subjects, mainly myological. About the time he accepted the chair at King's College he began to take an absorbing interest in embryology. In a lecture delivered there in 1908 he emphasised the need for visualising embryonic structures, and after describing His's method of model-making gave a vivid account and demonstration of Prof. Born's method of reconstruction by means of wax plates. He spent some time in Germany, working in Keibel's laboratory, where he acquired a knowledge of the various technical processes which are utilised in embryological work. He produced several papers of value, dealing with general conditions and special parts of young human embryos. These showed evidence, as did all Thompson's work, of care, thoroughness, and extensive knowledge of the literature of the subject in hand. He continued this embryological work after he went to Birmingham, but the disease which ultimately cut short his career soon began to affect his power of work; in fact, shortly before the beginning of the war, he said to a colleague that he felt he had done his work, and would do no more original research. He carried on his official duties, however, to the utmost extent that his strength would allow, and devoted much of his time to increasing the teaching scope of his department. As a teacher he was known far and wide. He combined a power of lucid exposition with an accurate and most extensive knowledge of the body, and communicated his enthusiasm to his students. Thompson utilised his knowledge of comparative anatomy and human embryology for purposes of exposition, but in his school such explanations were made subsidiary to the subject of descriptive anatomy, and were not converted into the main theme from which the human structure was suspended as an important appendage. He stood for complete acquaintance with descriptive anatomy as the necessary object of a student's work in the dissecting-room, and was no believer in the system of skimming over details asserted to be "of no practical importance."

Prof. Thompson had a lovable personality, and his death will be felt as a personal shock to many who knew him throughout the country, even though of late years he had rarely appeared in the gatherings of his former colleagues. He married in 1906 a daughter of the late Mr. G. L. Davies of Helsby, Cheshire, and had two sons.

GEORGE SAMPSON ELLISTON, C.B., V.D., M.R.C.S., L.S.A.

COLONEL, T.F. (RETD.)

Colonel G. S. Elliston, son of the late Dr. William Elliston of Ipswich, died at his residence St. Edmund's, Felixstowe, on Nov. 20th in his seventy-eighth year. He qualified M.R.C.S. and L.S.A. in 1866 from Guy's Hospital where he subsequently held house appointments, and later became house surgeon at the Royal Free Hospital and the East Suffolk Hospital, Ipswich. In 1872 Colonel Elliston became a general practitioner in Ipswich; a few years after he was appointed medical officer of health for the borough, and later held other appointments, including those of medical officer at the Isolation Hospital and medical officer of health to the Stamford Rural District. Before his tenure of office as medical officer of health a small-pox epidemic had visited Ipswich, revealing the insanitary condition of certain areas and, incidentally, the fact that there was no provision for dealing with infectious cases. The passing of the Public Health Act of 1875 therefore gave Colonel Elliston an opportunity of putting the town into a better sanitary condition. Old and unhealthy sites were cleared, an isolation hospital was built, and arrangements were made for the provision of a hospital ship. For some 32 years Colonel Elliston continued to work unceasingly in the cause of public health, and on his retirement received the unanimous thanks of the Corporation and the appointment as consulting medical officer for a further period of five years.

Colonel Elliston actively associated himself with the Volunteer movement and with the St. John Ambulance Association. He received his first commission as acting assistant surgeon in the 1st Suffolk Rifles in 1872, subsequently becoming surgeon lieutenant-colonel of the Suffolk Volunteer Infantry Brigade, P.M.O. of the East Anglian Territorial Division, and afterwards administrative medical officer of the East Anglian Division, Royal Army Medical Corps. He became an examiner for the St. John Ambulance Association in 1880 and an Honorary Associate of the Order in 1893, subsequently being made a Knight of Grace. He was made a C.B. in 1911 and retired in 1912, after 40 years service with the Volunteer movement.

Colonel Elliston belonged to a family well known in medical circles. His elder brother was the late Dr. W. A. Elliston, a former President of the British Medical Association and the father of the late Mr. Guy Elliston, for many years secretary of the Association, and of Mr. G. S. Elliston, editor of the *Medical Officer*, while his uncle, Dr. George Green Sampson, was four times mayor of his native city, Ipswich, an unusual civic honour for a medical man. His own father had a large practice in Ipswich, "so Elliston," writes an old friend and colleague, "when he settled down to practise in Ipswich after a term as house surgeon at the East Suffolk, had little need of introduction. But general and family practice had from the first small attraction for him. Medicine in its collective aspect was far stronger in its appeal to him. Ipswich in the 'sixties was mediæval in its insanitation—no general sewerage, no public scavenging, no means of isolating infectious disease, the privy-midden abounding—a fine field for the young sanitarian whose steps were deliberate and whose aim was pursued with conscientiousness. In connexion with another branch of social medicine, Elliston became more widely known. When, in 1878, the St. John Association started the civil ambulance movement, Elliston was a pioneer of it throughout and beyond East Anglia. Organising, training, lecturing, became his hobby. Its usefulness, the traditions of the ancient order, its simple pageantry, strongly appealed to him; a field day without his commanding presence, anywhere in the east and midland districts, seemed rate of 1·8 per 1000, compared with 2·1 per 1000 in 1919. The death-rate from tuberculosis in Belfast has fallen by 61 per cent. since 1890, and by 44 per cent. since 1900, the rate in 1920 being the lowest during the last 40 years. An analysis of cases arising in connexion with the various trades of the city shows that the higher figures were found in the following occupations: Clerks 17, carters 11, messengers 11, engineers 27, tobacco workers 18, doffers 26, drawers 11, laundresses 20, reelers 16, spinners 25, stitchers 40, winders 11. There were 100 cases amongst discharged soldiers, 122 cases amongst school boys, 142 amongst school girls, and 135 cases amongst housewives. Of 1186 patients found to be suffering from tuberculosis during the year 471, or over 39 per cent., have had personal association with tuberculosis amongst the members of their families. Dr. Trimble lays stress upon preventive measures, and the need for more attention to be given in the medical curriculum to the prevention of disease. According to Dr. Trimble the public are becoming more alive to the significance of early symptoms, and the importance of prompt diagnosis and treatment. The nurses in the employment of the Institute report improvement in the habits of the people, and a higher average of cleanliness. Dr. Trimble pleads for patience in estimating the results of anti-tuberculosis measures.

Queen's University of Belfast.

The Vice-Chancellor has presented to the Senate his report for the year 1920–21. The number of students in attendance was 1076, of whom 762 were men and 314 women. In the medical faculty the number was 588, 463 men and 125 women. The Medical Museum has been rearranged, and many new specimens, especially in the embryological collection, have been added. The new department of dentistry is now in full working order. During the year the students of the University undertook a street collection on behalf of this department. The sum of £1000 was realised and handed over to the Royal Victoria Hospital to equip the dental department of that institution. This department is now in possession of adequate premises and a full modern equipment.

The late Sir Joseph Michael Redmond, M.D.

Sir Joseph Redmond, past President of the Royal College of Physicians of Ireland, died suddenly on the morning of Nov. 25th at his residence, Merrion-square, Dublin. Although of late years he had reason to suspect some cardiac weakness, his health had recently given rise to no special cause for anxiety, and after a full and active day on Nov. 24th he retired to rest as usual. A few hours later he passed quietly away. He was 68 years of age. Sir Joseph Redmond's whole professional life was spent in Dublin. Having taken his qualification from the Royal College of Surgeons in 1878, he was for some time demonstrator of anatomy in the Catholic University School of Medicine. He was appointed one of the physicians to the Mater Misericordiæ Hospital, to which institution he gave devoted service up to his death. He became M.D. Brux. (honours) in 1890, and also received the M.D. N.U.I., *honoris causâ*. He held many posts as consulting physician to various charitable institutions, and acted as examiner to the Royal College of Physicians. He was Vice-President of the College from 1900 to 1902, and President from 1906 to 1908. On the termination of his office as President he received the honour of knighthood. He was a frequent contributor to medical literature. Sir Joseph Redmond was one of the most modest and unassuming of men, but with much quiet dignity; as a physician he was thoughtful and careful, and his abilities, together with the general confidence felt in his high character, assured him a lucrative practice as well as an honoured place in the profession.

LONDON (R.F.H.) SCHOOL OF MEDICINE FOR WOMEN.—A dinner will be held to-day, Friday, at the Connaught Rooms, Great Queen-street, London, W.C., at 7 for 7.30 P.M., Mr. James Berry presiding.

Correspondence.

"Audi alteram partem."

CLAYDEN *v.* WOOD-HILL.

To the Editor of THE LANCET.

SIR,—The facts of the case of Clayden *v.* Wood-Hill recently decided at the Suffolk Assizes, a short report of which appeared in your issue of Nov. 19th, when a verdict of £750 damages was given against a medical man for alleged negligence in the treatment of a fractured femur, should be studied by all medical practitioners. The plaintiff was thrown out of a trap and sustained a fracture of the upper third of the right femur. Two days later she was moved to the Beccles Cottage Hospital, in Suffolk, where Dr. Wood-Hill, of Beccles, attended her. The fragments united, and in eight weeks she returned home to Hertfordshire with strict instructions from Dr Wood-Hill that no weight was to be borne by the limb without the permission of her family doctor. A week later, when standing in her room at home, she felt the limb give way and she fell on to a sofa. Abundant evidence was produced at the trial that as regards splinting, extension, and position of the limb, the fracture was treated in accordance with modern methods while the plaintiff was an inmate of the Beccles Cottage Hospital.

The verdict of the jury largely turned on the question as to whether, at the second accident nine weeks after the first, a giving way of the previously united fragments took place. By very adroitly drawing from one item in the medical evidence bearing on this question an inference which, from a medical point of view, was entirely unjustifiable, counsel for the plaintiff induced the jury to bring in a verdict for the plaintiff with damages as stated. Many of those who watched the case throughout its course are convinced that a grave miscarriage of justice has taken place, and for this reason a fund has been started to reimburse Dr. Wood-Hill in the very heavy expenses incurred by him, which, we are informed, will amount, with costs, to about £1600. Naturally, the question of appeal has been very carefully considered, and Dr. Wood-Hill has been advised against this course by both his counsel and his solicitor.

It is true that at the time of the trial Dr. Wood-Hill was not a member of one of the Medical Defence societies, but this, although showing a lack of foresight on his part, is no reason for refusing to help him in this emergency. The fund will also serve as a token of the respect and esteem in which Dr. Wood-Hill is held in Beccles and the neighbourhood.

The following subscriptions have already been promised:—

	£	s.	d.
Mr. Hugh P. Helsham (Beccles)	26	5	0
Mr. John H. Allden (Beccles)	20	0	0
Mr. Christopher T. Helsham (Beccles), Sir Robert Jones (Liverpool), Mr. George E. Gask (London), Mr. R. C. Elmslie (London), Dr. Samuel J. Barton (Norwich), Dr. F. W. Burton-Fanning (Norwich), Sir Hamilton Ballance (Norwich), and Dr. Wilson Tyson (Lowestoft) .. .. each	10	10	0
Sir John Lynn-Thomas	10	0	0
Dr. H. Muir Evans (Lowestoft), Dr. C. B. Ticehurst (Lowestoft), Dr. D. W. Boswell (Lowestoft), Mr. J. C. Mead (Lowestoft), Mr. S. H. Burton (Norwich), Mr. Donald D. Day (Norwich), Dr. Sydney H. Long (Norwich), Mr. A. J. Blaxland (Norwich), Dr. R. W. Mullock (Southwold) .. .. .. each	5	5	0
Dr. D. H. Hutchinson (Lowestoft)	3	3	0
Mr. E. W. Everett (Norwich), Dr. H. J. Starling (Norwich), Mr. S. F. Smith (Beccles) .. each	2	2	0

Subscriptions should be sent to Sir Hamilton Ballance, Norwich, and will be acknowledged from time to time in the medical press.

We are, Sir, yours faithfully,
ROBERT JONES, JOHN LYNN-THOMAS.
GEORGE E. GASK, HAMILTON A. BALLANCE,
R. C. ELMSLIE, WILSON TYSON.
Nov. 26th, 1921.

⁂ Since our brief report of this case appeared on Nov. 19th (p. 1073) it has been made perfectly clear that while the X ray apparatus at the Beccles Hospital

Medical News.

University of Oxford.—The degree of B.M., B.Ch. has been conferred on D. G. T. K. Cross, St. John's College.—A War Memorial Scholarship of £100 per annum, and confined to intending medical students, is offered for competition at University College on Dec. 6th. Scholarships in natural science, most of which are open to intending medical students, are offered at University, Balliol, Oriel, Lincoln, Magdalen, Christ Church, and St. John's Colleges, examining in combination on Dec. 6th; and at Jesus College on Dec. 17th. *Appointment of Examiners*:—In Organic Chemistry: Edward Hope, M.A., Fellow of Magdalen College; in Human Anatomy: Prof. Arthur Thomson, M.A., Student of Christ Church; in Human Physiology: Martin W. Flack, B.M., M.A., University College; in Materia Medica and Pharmacology: Reginald St. A. Heathcote, D.M., New College; in Pathology: Prof. Henry Roy Dean, D.M., New College; in Forensic Medicine and Public Health: Francis J. Stevens, D.M., Exeter College; in Medicine: Harold Batty Shaw, M.D. Lond.; in Surgery: Sir William Thorburn, M.D. Lond.; in Obstetrics and Gynæcology: George H. A. Comyns Berkeley, M.B. Cantab.

University of Manchester.—At a meeting of the Court of Governors of the University of Manchester held on Nov. 16th it was stated that the number of students at present is 2711, of which 575 are new entries. There was a deficit of nearly £18,000, but the University appeal had now reached £231,851, apart from the £15,000 raised by a bazaar. Amongst gifts from towns Oldham had contributed £8355 and Stalybridge £3637. During the last five or six years the total expenditure on new buildings and equipment had been something like £100,000. The rush of students was responsible for involving the University in large and costly extensions, and the expenditure had doubled within the last five years. The Court approved the proposal to appoint as Professor Emeritus, Dr. E. S. Reynolds, professor of clinical medicine in the University from 1913 to 1921.

University of London: *Post-graduate lectures on Mental Deficiency.*—A course of lectures supplemented by a course of Clinical Instruction has been arranged by the University Extension Board in coöperation with the Central Association for the Care of the Mentally Defective. The clinical instruction will consist of visits to schools, homes, and certified institutions for the mentally defective, and demonstrations of individual cases of defect by experts to small groups of students. The course will be of two weeks' duration, beginning on Monday, June 12th, 1922. It is intended for qualified medical practitioners and more especially for those who are engaged as certifying officers to local authorities under the Mental Deficiency Act, 1913, as school medical officers, or as medical officers of institutions, or who are otherwise definitely concerned with defectives. The course will be based on the requirements of the syllabus for the University of London Diploma in Psychological Medicine, and the University will grant a certificate of attendance to those who have attended the whole course regularly, taking both theoretical and practical work. Lectures will be delivered at the University of London, South Kensington, by Dr. A. F. Tredgold, Dr. W. C. Sullivan, Dr. E. Prideaux, Dr. F. C. Shrubsall, Mr. Cyril Burt, and Miss Lucy Fildes. Each student will visit one special school and one large certified institution for defectives, and will attend demonstrations by the lecturers and other experts. The registration fee will be £1 1*s.*, and the fee for the course £5 5*s.* The course will only be held if a sufficient number of students are registered, and intending students are therefore asked to send in their applications as soon as possible to Miss Evelyn Fox, at the University of London, South Kensington, London, S.W. 7, from whom further particulars may be obtained.

The London Inter-Collegiate Scholarships Board announce the following Entrance Scholarships and Exhibitions for 1922:—Twenty-five scholarships and exhibitions of an aggregate total value of about £2920, open to men and women, and tenable in the faculties of arts, science, medical sciences, and engineering of University College, King's College, East London College, and Bedford College, will be offered for competition on May 2nd, 1922. Fifteen medical entrance scholarships and exhibitions of an aggregate total value of about £1300, tenable in the Faculty of Medical Sciences of University College and King's College, and in the Medical Schools of Westminster Hospital, King's College Hospital, University College Hospital, the London (Royal Free Hospital) School of Medicine for Women, and the London Hospital, will be offered for competition on June 27th, 1922. Full particulars and entry forms may be obtained from the Secretary of the Board, Mr. S. C. Ranner, the Medical School, King's College Hospital, Denmark Hill, London, S.E. 5.

Epsom College: St. Anne's Home Scholarship. The Council of Epsom College will shortly award a St. Anne's Home Scholarship of £12 a year to the orphan daughter, between the ages of 7 and 12, of a medical man. Full particulars can be obtained from the secretary, Mr. J. Bernard Lamb, at 49, Bedford-square, London, W.C. 1.

Voluntary Hospitals Commission.—Lord Cave, whose report on the voluntary hospitals led to the present scheme for assisting the hospitals, has agreed to serve on the Local Voluntary Hospital Committee for Surrey, as one of the members nominated by the Hospital Commission. Considerable progress has now been made in the establishment of Local Voluntary Hospital Committees in various parts of the country; and during the present week steps are being taken by the Commission to arrange for the preliminary meetings of the local committees for Cornwall, Derbyshire, Glasgow, Monmouthshire, Salop, Staffordshire, Surrey, Warwick, and Worcestershire.

Association of Economic Biologists.—A general meeting of this association will be held at 2.30 p.m. on Friday, Dec. 9th, in the Botanical Lecture Theatre of the Imperial College of Science, South Kensington, London, S.W. 7. The chair will be occupied by the President, Sir David Prain, and Prof. J. H. Priestley will open a discussion on The Resistance of the Normal and Injured Plant Surface to the Entry of Pathogenic Organisms. The hon. secs. of this association are Mr. Wm. B. Brierley and Mr. S. A. Neave, Rothamsted Experiment Station, Harpenden, Herts.

Prince of Wales's Hospital and North-East London Post-Graduate College.—A successful reunion dinner was held at the Trocadero Restaurant on Oct. 27th, with Dr. Arthur Giles in the chair. It was unanimously decided that a reunion association in connexion with the hospital and post-graduate college be formed, and a committee was appointed for this purpose. All inquiries and communications should be addressed to the hon. secretaries, Dr. Jenkins Oliver, 1, Devonshire-place, London, W. 1, and Mr. S. O. Rashbrook, 15, Gordon-street, London, W.C. 1.

Newcastle-upon-Tyne and Northern Counties Medical Society.—The annual address will be delivered in the library of the Royal Victoria Infirmary on Friday, Dec. 9th, at 4.45 p.m., by Mr. Herbert Tilley. The subject will be Some Common Diseases of the Ear, Throat, and Nose. The annual dinner will be held the same evening in the Grand Assembly Rooms, Barras Bridge, Newcastle-upon-Tyne, at 7.15. Tickets, at 15*s.* each, can be obtained from Mr. Norman Hodgson, 11, Jesmond-road, Newcastle.

Donations and Bequests.—By will the late Sir Frederick Thomas Edridge, J.P., of Bramley Croft, Croydon, Surrey, has left £5000 in trust to pay the income to the Croydon General Hospital while it shall remain an institution of which not less than one-half of the cost of maintenance shall be provided by voluntary contributions; £1500 each to the Surrey Convalescent Home for Men, Seaford, and the Children's Convalescent Home, Bognor; £1000 each to the Croydon General Hospital and the Victorian Convalescent Home for Women, Bognor; and £500 to the Beddington Female Orphan Asylum. These bequests, however, do not take effect during the lifetime of the testator's wife.

Royal Dental Hospital: Annual Dinner.—The annual dinner of the staff, past and present students of the Royal Dental Hospital of London, which took place at the Hotel Victoria on Nov. 26th, was well attended by all sections of the School, senior and junior. Dr. H. Austen, who presided, while expressing satisfaction with the progress of the Dental School in many directions, lamented the absence of research laboratories and of sufficient accommodation for the treatment of in-patients. Mr. H. Stobie, dean and director of the studies at the School, reviewed the last academic year, with its grand total of 316 students and pupils, and noted an entry this session of 80. The overcrowding in the mechanical department had now passed on into the operating department, where its effects were still felt. The staff had been increased by two extra honorary anæsthetists and by the appointment of Dr. Stanley Colyer as assistant radiologist. He welcomed the institution by London University of a bachelorship in Dental Surgery which was only awaiting its curriculum. The new appointment of medical registrar in the School was giving dental dressers for the first time a comprehensive view of morbid conditions in the mouth. Miss L. B. Aldrich-Blake, dean of the London School of Medicine for Women, responded to the toast of "The Visitors," and the arranged programme, which included excellent glee singing, ended with a felicitous speech from Mr. W. H. Dolamore in proposing the chairman's health.

urine varies directly with the amount of urea present and that in the two-hourly specific gravity test for renal efficiency the point on which stress is laid—namely, the variation of more than eight degrees—depends on the excretion of urea and water primarily, chlorides to a less extent. The close parallelism is between the S.G. of the urine and the percentage of urea. The S.G. was estimated with the pyknometer and the urea percentage found by the technique and calculation devised by Prof. H. MacLean.

I am, Sir, yours faithfully,

Clifton, Bristol, Nov. 27th, 1921. CECIL CLARKE.

THE ORIGIN OF VACCINATION.

To the Editor of THE LANCET.

SIR,—In his profoundly interesting inaugural address before the Midland Medical Society at Birmingham on Nov. 2nd (THE LANCET, Nov. 26th, p. 1139), Prof. W. D. Halliburton is reported to have said:—

> "Such excursions of the imagination may not come into the domain of exact knowledge, but they have led to understanding of such an operation as vaccination—*a purely empirical procedure in Edward Jenner's day*—and have enabled practical men to devise corresponding means for the prevention or cure of other diseases."

In this pretension (the italics are mine) I must join issue, as the right understanding of the evidence is of such importance to the whole world, and its correct inference was never of greater importance than now when vaccination has become unmeaning amongst the uneducated in this country, largely from the misunderstanding of the facts.

What are the facts? When ascertained they were certainly not excursions of the imagination, nor were they empirical. In 1774 Benjamin Testy, a Gloucestershire farmer, to save his family from the hideous disfigurement and blindness occasioned by small-pox (the plainest of women were considered beautiful when unscarred by it) as well as its appalling mortality, inoculated with cow-pox his wife and two sons for the purpose of protecting them from small-pox. He succeeded, and had the honour of being "stoned" and reviled by his neighbours. What led him to inoculate them was the popular tradition of the district, incited mainly by the hilarity of the dairy-maids who milked the cows, and who jeered at the thought of catching small-pox when they had already contracted cow-pox in their daily occupation.

In 1796, the immortal Edward Jenner, the inoculator of small-pox in his district in Gloucestershire, after weighing all the evidence he had gained, had the courage to carry out his closely reasoned conclusions that the facts were unassailable, and established on sure ground the practice of vaccination which the whole world gripped after the usual period of opposition and calumny.

I am, Sir, yours faithfully,

Rugby, Nov. 25th, 1921. CLEMENT DUKES.

EQUITY IN HOSPITAL APPOINTMENTS.

To the Editor of THE LANCET.

SIR,—The gift of being able to touch a sore spot without provoking pain is denied to most, but this ideal is very nearly achieved by Sir Clifford Allbutt in THE LANCET of Nov. 5th, in his candid yet courteous discussion of the election of candidates for honorary hospital appointments. He writes:—

> "It is easy now, when good appointments have been made in the London University, to say, nevertheless, that the mode leaves something to be desired. At present the election is virtually in the hands of the honorary staff of the hospital concerned. It is true that hitherto the hospital staffs have used their power loyally and with moderation; but this gives us no guarantee for the future. In the London University it would be better for the Senate to establish standing election committees, renewed by rotation, of independent—that is, ad hoc unofficial—persons of distinction in the several parts of medicine. The hospital staff would thus be relieved of the duty not only to consider the claims of particular interests or promotions, but also those of past services or private friendships."

Every large hospital has its secret history of staff election politics, and if we are to believe unsuccessful candidates, many first-rate men are now eating their hearts out because their rivals had other support than that of their intrinsic merits. What are the qualifications, primary and secondary, required, and who are the best judges thereof? On the second point Sir Clifford Allbutt is perfectly explicit, and few will join issue with him on it, though the principle for which he pleads seems to have been honoured chiefly in the breach. But what of the qualifications for these appointments? What, if any, importance is to be attached to "breeding," eminence in athletics, suavity, and the many other social qualifications which count in the election of an aspirant to membership of an exclusive upper-middle-class club? We know that the possessor of these qualifications succeeds better in life than the man who looks like a drain rat, runs amuck with his aspirates, and adopts a frankly irreverent attitude towards incompetence in high places.

The first type may be personally more attractive than the second, but it is well to remember the oft-quoted dictum of head masters that the popular school boy seldom rises above mediocrity, and that a shaggy exterior and uncouth manners may hide genius. An old frequenter of medical congresses once said that their chief value lay in the opportunities they afforded of studying prominent men hitherto known only by their writings. And he revised his estimate of the written word according as the authors thereof gave a good or bad impression when they spake. Is this test sound? Against it might be cited the case of Moses, St. Paul, and many another intellectual giant without "presence" and unable to shine on a platform. Many a man of minor gifts has bluffed his way to eminence by sheer force of speciousness. In his "Life of Gladstone" Lord Morley tells of an Oxford don who always looked as if he was going to say something witty. It was not till a critical observer remarked that he never got beyond this stage that his reputation as a wit was shattered. It is, of course, very difficult to appraise the qualifications of candidates for honorary hospital appointments, but the unsuccessful candidate, convinced of the inferiority of his successful rival, may find consolation in the reflection that, when mediocrity backed by nepotism prevails, the iconoclastic judgment of students at the large teaching hospitals soon leaves naked the nether part of the idol with feet of clay.

With regard to resident hospital appointments, the selection of candidates is usually quite fair, and they are now seldom expected personally to canvass the members of the senior honorary staff. I do not wish to sign this, as it might appear that I was making personal reflections, but you, Sir, will recognise that I am, as well as yourself,

Nov. 14th, 1921. QUITE DISINTERESTED.

SWIMMING FACILITIES FOR BLIND CHILDREN.—Some time ago the Education Committee of the London County Council was authorised to consider whether facilities with regard to swimming should be provided for children attending the Council's schools for the blind. After careful consideration and consultation with the managing committees of the schools in question, the Education Committee has reported to the Council that, in their opinion, it would be inadvisable to proceed further with the suggestion. The Council has, therefore, decided that no provision for swimming shall be made.

THE LATE DR. W. H. SMART.—William Herbert Smart, who died suddenly on Nov. 5th, after an operation, at a nursing home in Birmingham, aged 59, was the only son of the late Sir William Richard Edwin Smart, K.C.B., R.N., and was educated at Caius College, Cambridge, and at St. Thomas's Hospital. He graduated in 1882, and became M.A., M.B. in 1886, having in the previous year obtained the M.R.C.S. Eng. After holding a house appointment at St. Thomas's Hospital he was resident clinical assistant at the East London Hospital for Children, and later entered upon medical practice at Polesworth, near Tamworth, where for upwards of 30 years he was medical officer of the district under the Atherstone Board of Guardians. In 1897 he contributed to our columns a note on a case of tetanus successfully treated by antitoxin.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Wednesday, Dec. 7th.

SOCIAL EVENING: A Social Evening will be held on Wednesday. The usual social programme will be provided, but, in addition, Sir Berkeley Moynihan will deliver a short address on "Medicine in Art," with lantern illustrations. The President and Lady Bland-Sutton will receive at 8.30. Fellows are welcome to invite any of their friends, including ladies, and no tickets of admission are required.

MEETINGS OF SECTIONS.

Monday, Dec. 5th.

TROPICAL DISEASES AND PARASITOLOGY: at 8.30 P.M.
Discussion: on "Amœbic Dysentery in Great Britain: its Significance and Treatment." To be opened by Dr. Broughton-Alcock. Prof. Warrington Yorke and Dr. P. Manson-Bahr will also speak.
Paper:
Dr. M. Khalil: Thermotropism in Ankylostome Larvæ.

Tuesday, Dec. 6th.

SURGERY: SUB-SECTION OF ORTHOPÆDICS: at 5.30 P.M. (Patients' Casts and Photographs at 5 P.M.)
Discussion:
On "Stabilising Operations in the Treatment of Paralytic Deformities of the Foot," to be opened by Mr. Naughton Dunn (Birmingham).
The President (Mr. Laming Evans), Mr. Bankart, Mr. Aitken, and others will take part in the Discussion.

PATHOLOGY: at the Lister Institute, Chelsea-gardens, S.W.3: at 8.30 P.M.
Dr. V. Korenchevsky: Experimental Rickets in Rats, with Demonstration of Specimens. Dr. G. Ségal: The Association of Typhus Virus with the Various Blood Elements. Mr. A. W. Bacot: Demonstration of Rectal Infection of Lice by Weigl's Method. Mr. A. W. Bacot and Dr. G. Ségal: The Development of Rickettsia in Lice, following Intrarectal Infection with Typhus Virus. Dr. R. St. John Brooks and Dr. M. Rhodes: Some Observations on the Hæmorrhagic Septicæmia Group. Miss E. H. Lepper: Gall-bladder Infections following the Intravenous Inoculation of Coliform Organisms in Rabbits. Dr. S. P. Bedson: Demonstration of Histological Material from Experimental Purpura. Dr. S. Kanai: Dysentery Immunisation per os.

Wednesday, Dec. 7th.

SURGERY: at 5.30 P.M.
Papers:
Sir Charles Ballance: Ligation of the Innominate Artery.
Sir Lenthal Cheatle: A New Operation for Inguinal Hernia.

Thursday, Dec. 8th.

BALNEOLOGY AND CLIMATOLOGY: at 5.30 P.M.
Paper:
Dr. A. G. S. Mahomed: The Relation of Atmospheric Electrical Variations to the Incidence of Epileptic Fits.
Discussion on the Organisation of the Section.

NEUROLOGY: Clinical Meeting at the Hospital for Paralysis, Maida Vale, at 8 P.M.

Friday, Dec. 9th.

CLINICAL: at 5.30 P.M. (Cases will be shown at 5 P.M.)

ELECTRO-THERAPEUTICS: at 8.30 P.M.
Informal Meeting: Tea, Talk and Tobacco.
Dr. Carelli, of Buenos Aires, will give a Demonstration of his "Method of Radioscopic Examination with the Help of Gas Injections." Dr. Riddell will also give a Demonstration of a "Simple Apparatus for Making Serial Radiographs of the Pyloric Region in the Horizontal and Upright Positions."

OPHTHALMOLOGY: at 8.30 P.M. (Cases at 8 P.M.)
Clinical Evening.

HUNTERIAN SOCIETY, Sion College, Victoria Embankment, E.C. 1.
Wednesday, Dec. 7th.—9 P.M., Sir Henry J. Gauvain: Surgical Tuberculosis (illustrated by lantern slides).

HARVEIAN SOCIETY OF LONDON, Rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, W.
Thursday, Dec. 8th.—8.30 P.M., *Discussion:* Is the Anginal Syndrome only of Cardiac Origin? Opened by Sir John Charlton Briscoe, followed by Sir Sydney Russell-Wells, Dr. G. H. Hunt, and Sir William Willcox.

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.
Monday, Dec. 5th.—General Meeting at 122, Harley-street, at 4 P.M., A Discussion on The Place of the Colony in the Tuberculosis Scheme, will be opened by Dr. S. Tinker, and a Discussion on The Place of the Sanatorium at Present and in the Future, will be opened by Dr. Noel Bardswell.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
Monday, Dec. 5th.—5 P.M., Dr. Arthur Saunders: Digestive Disorders of Old Age; Carcinoma of the Stomach.
Tuesday.—5 P.M., Mr. Addison: Intravenous Therapy.
Wednesday.—5 P.M., Mr. Page: Anæsthesia.
Thursday.—5 P.M., Mr. Bishop Harman: Congenital Cataract.
Friday.—5 P.M., Dr. Pritchard: Blood Pressures.
Daily:—10 A.M., Visit of Post-Graduates to Wards. 2 P.M., In-patient, Out-patient Clinics and Operations.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART POST-GRADUATE COURSE, Westmoreland-street, Marylebone, W.
Monday, Dec. 5th.—5.30 P.M., Lecture: Dr. Parsons-Smith: Infective Endocarditis.
Daily:—10 A.M. and 2 P.M., Out-patients and In-patients.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
Thursday, Dec. 8th.—4 P.M., Lecture: Mr. H. A. T. Fairbank: Coxa Vara.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE CLINIC.
Tuesday, Dec. 6th.—4.30 P.M., Dr. F. E. Tylecote: The After-treatment of Pneumonia.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURE, Whitworth-street West Branch, Manchester.
Friday, Dec. 9th.—4.30 P.M., Dr. Fletcher Shaw: Ante-partum Hæmorrhage.

ANCOATS HOSPITAL.
Thursday, Dec. 8th.—4.30 P.M., Mr. Harry Platt: The Diagnosis and Treatment of the Common Affections of the Hip-joint.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.
Wednesday, Dec. 7th.—4 P.M., Lecture VIII.:—Sir Kenneth Goadby: Lead Poisoning in Industry.

UNIVERSITY OF SHEFFIELD—FACULTY OF MEDICINE. Post-Graduate Lectures and Demonstrations.
Tuesday, Dec. 6th. (At the Royal Hospital.)—3.30 P.M., Prof. Douglas: Vaccines. 4.15 P.M., Mr. V. Townrow: Demonstration of Cases.
Friday. (At the Royal Hospital).—3.30 P.M., Dr. G. Wilkinson: Diagnosis of Diseases of the Accessory Sinuses of the Nose. 4.15 P.M., Dr. G. Wilson: Orthopædics.

CHADWICK PUBLIC LECTURES, Barnes Hall, Royal Society of Medicine, 1, Wimpole-street, W.
Thursday, Dec. 8th.—8 P.M., Dr. Charles Singer: History of the Doctrine of Infection.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
Thursday, Dec. 8th.—6 P.M., Chesterfield Lecture:—Dr. W. Griffith: Eczema.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Monday, Dec. 5th.—4.30 P.M., Dr. J. Bright Bannister: Some Obstetric Emergencies.
Tuesday.—3.30 P.M., Dr. F. G. Crookshank: Physical Examination of the Chest (3)—The X Rays.
Friday.—4.30 P.M., Dr. C. E. Sundell: The Clinical Diagnosis of Tuberculosis in Children.
Daily:—2.30 P.M., In-patient, Out-patient Clinics, Operations, &c.

Appointments

McDonald, N., M.B., Ch.B. Vict., M.R.C.S. Eng., L.R.C.P. Lond., has been appointed Hon. Anæsthetist, Metropolitan Ear, Nose, and Throat Hospital, Fitzroy-square, W.

Thomson, E. G., M.D., B.Ch. Aberd., to be one of the Medical Referees under the Workmen's Compensation Act, 1906, for the Sheriffdom of Forfar.

Certifying Surgeons under the Factory and Workshop Acts: Skeggs, B. L., M.R.C.S., L.R.C.P. Lond. (Stevenage); Strachan, A., M.B., Ch.B. Edin. (Finedon).

Vacancies.

For further information refer to the advertisement columns.

All Saints Hospital for Genito-Urinary Diseases, Vauxhall Bridge-road.—Res. H.S. £160.

Bedford County Hospital.—Asst. H.S. £150.

Birmingham, City Hospital for Infectious Diseases.—Temp. Asst. M.O. £350.

Birmingham Ear and Throat Hospital.—H.S. £200.

Birmingham General Dispensary.—Res. M.O. £500.

Birmingham, Queen's Hospital.—Obst. and Ophth. H.S. Each £90.

Bridgend, Glamorgan County Asylum.—Jun. Asst. M.O. £415.

Bristol General Hospital.—Hon. M.O. Hon. Med. Reg. Hon. Clin. Assts.

Bristol Royal Hospital for Sick Children, &c.—H.P. £150.

Burnley, Victoria Hospital.—H.S. £200.

Bury Infirmary. Jun. H.S. £150.

incomplete. At meetings of all kinds his presence was much in demand for his persuasive and genial speech."

The attendance at his burial in Old Felixstowe Church on Nov. 24th was evidence of the large circle of friends among whom Colonel Elliston was held in affectionate regard.

SIR SYDNEY BEAUCHAMP, M.B., B.CH. CAMB.

Sir Sydney Beauchamp, who died in London on Nov. 22nd as the immediate result of an accident, will be deeply regretted by an unusually large circle of friends, as well as by patients and colleagues. He had for many years been in practice in the West End of London, and his skill and devotion to his patients were as marked as the modesty with which he received success and attained to a high place in our professional ranks.

Sydney Beauchamp was born at Bexley, Kent, in 1861, and was educated at Gonville and Caius College, Cambridge, where he graduated in the natural science tripos in 1887. Proceeding to St. Bartholomew's Hospital he took the English double qualification in 1889, and in the following year the Cambridge degrees of M.B., B.Ch. At St. Bartholomew's Hospital he held several minor appointments, among others that of assistant electrician, but it was in general practice, and especially as a skilful obstetrician, that he made his mark. The outbreak of war found him too old for immediate service abroad, but he was made responsible for the organisation of Wrest Park as a military hospital. This was in September, 1914, and he remained its chief medical officer until it was destroyed by fire. It was the admirable work that he did at this hospital, and the devotion which he displayed as physician to the lying-in hospital of the Officers' Families Fund, which brought Beauchamp's name to the notice of the authorities and led to his invitation to accompany the British Delegation to the Peace Conference in Paris as its medical officer. In 1920 his name appeared in the Birthday Honours as having been granted a civil knighthood, a distinction that was thoroughly well deserved.

It is a tragedy that so useful a life should have been cut off in its prime, for although Beauchamp had reached 60 years of age he was an essentially young and energetic man, clear-headed, helpful, and untiring. The expressions of regret at his tragic death which have appeared in the public press represent in his case more than lip-service.

H. E. CORBIN, B.Sc. LOND., M.R.C.S., D.P.H.,

MEDICAL OFFICER OF HEALTH, STOCKPORT.

Dr. Herbert Ernest Corbin, M.O.H. Stockport, died at his residence in Stockport on Nov. 24th at the early age of 49. Dr. Corbin took the degree of B.Sc. Lond. in 1897 and qualified M.R.C.S. and L.R.C.P. in 1903, having won from St. Mary's the Senior University Exhibition. After qualifying Dr. Corbin took the D.P.H. in 1905 and held many appointments, including that of medical superintendent of the London Fever Hospital and assistant M.O.H. at Croydon and Willesden. His publications show that his interests were specially directed towards the prevention and treatment of small-pox. He was appointed M.O.H., Borough School M.O., and medical superintendent of the Isolation and Small-pox Hospitals of Stockport in 1908, where he organised the public health department and brought it to a high state of efficiency. Dr. Corbin was joint author (with A. M. Stewart) of a "Handbook of Physics and Chemistry," which reached its fifth edition in 1920. His war record was distinguished. When war broke out he was medical officer of the Manchester Artillery and after mobilisation was appointed special sanitary officer to the 66th East Lancashire division. He then became Major in the R.A.M.C., T., served in Mesopotamia with the rank of Lieut.-Colonel, and during 1917–18 was M.O.H. at Bagdad. Dr. Corbin is survived by a widow and two children.

JOHN SCOTT, M.A., M.D. ABERD.

THE death of Dr. John Scott, formerly of Manchester, took place at Abridge, Essex, on Nov. 22nd. Dr. Scott graduated as M.A. in the University of Aberdeen in 1866, took the degrees of M.B. and C.M. at the same University in 1873, and became M.D. in 1891. He then settled in Manchester in general practice; he was honorary physician to the Manchester Southern Hospital for Diseases of Women and Children—now incorporated in St. Mary's Hospitals—and for several years was lecturer and instructor in vaccination in the University of Manchester. Possessed of wide academic culture Dr. Scott also had literary ability and knowledge of languages, and was thus an expert scientific translator. Some years ago his health began to fail and he retired from his Manchester duties to reside at Abridge with his son, Dr. J. Bethune Scott, at whose house he died at the age of 73.

The Services.

ROYAL NAVAL MEDICAL SERVICES.

Surgn.-Cmdr. H. H. Gill is placed on retired list at own request, with rank of Surgn.-Capt.

Surgn.-Lieuts. L. S. Goss and A. G. Taylor to be Surgn. Lieut.-Cmdrs.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. H. A. L. Howell retires on retired pay on account of ill-health caused by military service, and is granted the rank of Col.

Capt. F. P. Rankin retires, receiving a gratuity, and is granted the rank of Maj.

Capt. P. A. With is restored to the establishment.

Temp.-Lt. H. C. Perkins to be Temp. Capt.

Temp. Capts. relinquishing their commns., and retaining the rank of Capt.: J. T. Rearden, T. E. Dobbs, E. H. Griffin, J. MacRae, J. G. Castellain, and E. D. Lindow.

ARMY DENTAL CORPS.

Temp. Capt. W. Philp, Dental Surg., from Spec. List, to be Capt.

Acting Capt. G. W. Allen, from Unempld. List, R.A.F., to be Lt., and to be temp. Capt.

TERRITORIAL ARMY.

Capts. H. R. Moxon and H. F. Humphreys to be Majs.

Majs. A. B. Whitton and J. M. Bowie resign their commns. and retain the rank of Maj., with permission to wear the prescribed uniform.

Capt. A. S. Walker resigns his commn. and retains the rank of Capt.

The following relinquish their commns: Lt.-Col. J. P. S. Ward, with permission to wear the prescribed uniform: Capts. T. L. de Courcy, C. B. Alexander, H. B. Cunningham, and T. J. Costello.

2nd W. Genl. Hosp.—Capt. E. D. Telford, having attained the age limit, is retired, and retains the rank of Capt.

2nd S. Genl. Hosp.—Capt. W. Cotton, having attained the age limit, is retired, and retains the rank of Capt.

TERRITORIAL ARMY RESERVE.

Lt.-Col. A. M. McIntosh from Genl. List, R.A.M.C., to be Col.

Maj. R. E. Williamson (Lt.-Col. and Hon. Col., Ret., T.F.), having attained the age limit, is retired, and retains his rank, with permission to wear the prescribed uniform.

Capts. D. E. Finlay and J. H. Jordan, from R.A.M.C., Genl. List, to be Majs.

Capt. J. McG. Deuchars resigns his commn. and retains the rank of Capt.

ROYAL AIR FORCE.

Group Capt. (actg. Air Commodore) M. H. G. Fell (Lt.-Col., Bt.-Col., R.A.M.C.), relinquishes his temporary commission on return to army duty.

Group Capt. D. Munro is appointed Director of Medical Services, Air Ministry, vice Group Capt. (actg. Air Commodore) M. H. G. Fell.

Flight-Lt. W. G. L. Wambeek is granted a short service commission in the rank stated, retaining his present seniority.

The undermentioned are granted short service commns. as Flying Officers: E. C. K. H. Foreman, W. J. G. Walker.

J. Paxton is granted a temporary commn. as a Flight-Lt.

whilst 47,851 were criminally inflicted. Death occurred as a result of injuries in 5617 of the cases examined, of which 1640 were cases of criminally-inflicted injuries.

Hospital Accommodation.

It is recorded with satisfaction, as a proof of increasing public interest in the provision of hospital treatment for the poor, that during the year several notables have interested themselves in collecting funds and have personally given very generous donations of money and land for the building and upkeep of new hospitals. The existing ones are most inadequate in number and size for the population. The Government have accepted from Messrs. Thomas Cook and Son the liberal gift of the freehold building and equipment of their hospital at Luxor, and it is hoped that this institution will shortly be reopened. A sum of £E.500 has been privately subscribed to supply Kena Hospital with an electric plant for lighting and X ray work.

During the war the military accommodation provided for the sick and wounded from the forces in Egypt, Palestine, and Gallipoli had to be supplemented by the use of the Egyptian Government hospitals under the public health administration for the reception of a portion of these, and 44,630 sick and wounded were actually treated in these hospitals during the years 1914–19. With the cessation of hostilities the necessity for this has gradually diminished, so that last year provision had to be made for only 407 military cases. There has consequently been a reduction in the general number of in-patients from 64,704 in 1919 to 62,493 in 1920. On the other hand, the number of out-patients has increased from 219,573 in 1919 to 274,557 in 1920, the number of attendances having been 578,789, or roughly two per patient. The number of major operations performed increased from 9051 to 12,797. Special anthelmintic annexes similar to that attached to Kasr-el-Aini Hospital at the end of 1919 were established in connexion with the Qaliub, Benha, and Mansura general hospitals for the free treatment of out-patients suffering from ankylostoma, bilharzia, and other worm infections. This is intended to form part of a general campaign against ankylostoma and bilharzia in Egypt. The number of out-patients treated since the opening of these annexes is 14,905. Of these, 1905 were infected with ankylostoma and 13,000 with bilharzia. The seven schools for training native midwives in provincial towns continued to do good work and remained open throughout the year. These centres are becoming increasingly popular both with the general public and with the medical profession. The 13 children's dispensaries worked continuously through the year, except that at Assiut, which was closed on the ground of lack of funds. Though simple remedies are prescribed for the sick children attending the dispensaries, these institutions are also infant welfare centres, where the mothers receive instruction in the care of their children, in simple hygiene, correct methods of feeding, suitable clothing, &c., and above all the matrons try to inculcate habits of cleanliness. This is a difficult matter under the primitive housing conditions which prevail, with the total lack of water-supply or of any lavatory accommodation, but some progress is evidenced by the cleaner faces and clothing of the children attending the dispensaries. The total number of attendances in 1920 was 301,703 and the number of children receiving treatment was 56,462.

Since 1903, when Sir Ernest Cassel made his gift of £E.40,000 for the purpose of providing centres of ophthalmic treatment, the scope of this branch of the medical service has gradually increased until at present there are 20 hospitals provided for the purpose of affording treatment to sufferers from eye disease. Of these, 5 are travelling hospitals, which are moved as required from place to place, and 15 are permanent. The number of patients treated in 1920 was 91,921, of whom 4232 were actually admitted into hospital. A special ophthalmic hospital is urgently required in Cairo. It is now impossible to cope with the vast number of patients who come demanding operations to relieve in-growing eyelids and eyelashes—one of the cicatricial results of trachoma—whilst there is also insufficient ophthalmic relief in Cairo for the thousands who suffer, especially during the hotter months of the year, from painful and destructive diseases of the eye. There is therefore a pressing necessity for a centrally situated hospital equipped with 100 beds and able to treat 2000 out-patients daily in the summer.

Infectious Diseases.

The incidence of infectious disease during 1920 was exceptionally low. There was a reduction of 60 per cent. in small-pox, 48 per cent. in plague, 22 per cent. in typhus, and 12 per cent. in relapsing fever. One case of cholera occurred at Suez in the summer. There was a slight rise in the number of cases of malaria, probably in large measure the result of the fuller notification of cases. During the year 34,173 passengers and immigrants from countries infected with cholera landed in Egypt. Measures of control and observation at their destinations were applied to 33,578 of these, and no cholera infection showed itself. Land passengers from Palestine were similarly controlled for all diseases. Difficulties of ordinary transport obliged the Government to charter a steamer for the transport of the Egyptians making the pilgrimage to Mecca, the number being 1658 in addition to the Mahmal escort and staff of 507. Before their departure all pilgrims were vaccinated against cholera. No regular visit was made to Medina, but in view of the possibility of pilgrims paying clandestine visits to that place and escaping observation by returning over the Medina railway, on which there are no regular quarantine arrangements, a system of patrols was instituted in the Sinai Peninsula for the purpose of intercepting any pilgrims who might enter Egypt directly from Arabia or through Palestine. Fifteen such pilgrims were intercepted by these patrols and put under observation. No cholera was reported from the Hedjaz and none occurred amongst the returning pilgrims.

Laboratory Examinations.

The total number of examinations carried out in the laboratories during the year was 18,411, as compared with 15,050 in 1919, showing, as before, a steady increase. 10,098,720 doses of vaccine lymph were prepared in the Vaccine Institute in 1920 as compared with 5,645,020 in 1919, this considerable increase being due to the fact that the Epidemic Service of the Public Health Department undertook a large campaign of general revaccination with the object of stamping out or reducing the continual occurrence of small-pox in Egypt. In 1920 1228 persons were treated in the Antirabic Institute. Most of these had been bitten by dogs, but cases of bites by such diverse animals as cats, wolves, monkeys, donkeys, horses, mules, camels, jackals, and rats were also treated. Two persons bitten by a rabid human being likewise received treatment.

During the last 12 months the Anti-Malaria Commission has spent considerable sums of money in filling in breeding-places of mosquitoes or draining them, and in the case of large bodies, stocking them with larvæ-eating fish. Special work has been carried out in the oasis of Siwa and Kharga, where malaria of a severe type was rampant. Careful spleen examination work has been carried out by the Public Health Department, and as a result it is proposed now to deal with a number of sites (especially in the Fayum) where such efforts appear most necessary. The Commission is satisfied that there is no immediate danger of the rapid increase of malarial infection in Egypt, but at the same time is of opinion that a careful watch should be kept on this disease, and that steady continuous work should be done to get rid of all possible sources of infection.

(*To be concluded.*)

INFECTIOUS DISEASE ON ACTIVE SERVICE: THE AMERICAN EXPEDITIONARY FORCE.

In the *Military Surgeon* for October Dr. Haven Emerson of New York gives account of the communicable diseases which occurred in the American Expeditionary Force in France from July, 1917, to May, 1919. Diphtheria (4714 cases, 62 deaths, case mortality 1·3 per cent.) was brought over to France early by the 32nd and 35th Divisions, but later contracted by infection from the French civil population, more numerous in the less devastated American zone. At Mesves wound diphtheria occurred; it did not cause the usual toxæmia, and was not controlled by the injection of anti-diphtheritic serum. In the British Army, it may be remarked in passing, the infected wounds were dressed with anti-diphtheritic serum. Mumps (82,000 cases, 43 deaths, case mortality 0·05 per cent.) was, as ever, an important disease in an army of young men, for it meant 1500 hospital beds constantly occupied, and 4500 at one time in December, 1918. Measles (8207 cases, 86 deaths, 1·05 per cent. case mortality) became insignificant after new troops ceased to arrive. Its extreme contagiousness was a challenge to employ every precaution; daily or twice daily inspections, segregation, enforced hygiene were the principal safeguards. Cerebro-spinal fever (1965 cases, 911 deaths, case mortality 46 per cent.) appeared mostly at the bases, being contracted in crowded transports where each man had only 9 square feet of area. It was most frequent in October, 1918, with influenza prevalent and the coöperation of cold, wet weather, over-crowding and exhaustion. Scarlet fever (2064 cases, 70 deaths, case mortality 3·39 per cent.) occurred mostly at the beginning of the campaign; it was communicated in the transports and was easily controlled. The diagnosis of cases of dysentery does not seem to have been so vigorously determined by the laboratory as in the French and English armies. It is noted that there were 150,000 cases of diarrhœa in the 1st Army in July, 1918. Such a strain on the administrative machinery must have determined to some extent the fortunes of that month.

DENTAL BOARD OF THE UNITED KINGDOM.—The constitution of the Dental Board of the United Kingdom is as follows: Mr. Francis Dyke Acland, M.P. (Chairman); Mr. Laurence George Brock; Mr. Fred Butterfield; Sir Arthur Gerald Chance, F.R.C.S. Irel.; Mr. Dugald McCoig Cowan, M.P.; Mr. William H. Dolamore, M.R.C.S., L.D.S.; Prof. William Henry Gilmour, M.D.S., L.D.S.; Mr. William Guy, F.R.C.S. Edin., L.D.S.; Sir James Hodsdon, F.R.C.S. Edin.; Mr. Horace Archibald Robertshaw; Mr. Edward Leo Sheridan, F.R.C.S. Irel., L.D.S.; Mr. John Sinclair; Mr. Holburt Jacob Waring, F.R.C.S.; and Mr. Norman C. King, Registrar. The offices of the Dental Board will be at No. 44, Hallam-street, Portland-place, London, W. 1. All communications should be sent to the Registrar at that address.

HUNTERIAN SOCIETY.—A meeting will be held on Wednesday, Dec. 7th, at 9 P.M., at Sion College, Embankment, London, E.C. Sir Henry Gauvain will read a paper on "Surgical Tuberculosis," which will be illustrated by lantern slides. All members of the medical profession are cordially invited to attend.

NATIONAL COUNCIL FOR COMBATING VENEREAL DISEASES: SCOTTISH COMMITTEE.—A Conference of representatives of local authorities and others interested in the prosecution of active measures in Scotland for combating venereal diseases will be held in the City Chambers, Glasgow, to-day, Friday, Dec. 2nd. In the morning the Conference will be addressed by Sir Malcolm Morris and Sir Leslie Mackenzie, and in the afternoon by Dr. M'Gregor-Robertson, Dr. A. R. Chalmers, Dr. G. Y. Richardson, and Dr. J. A. Third.

BIRMINGHAM HOSPITAL SATURDAY FUND.—The amount of this year's collection is £58,768, and when a few outstanding contributions have been received it is estimated that the total will be £60,000, or about the same as last year. After providing for the maintenance of the Fund's convalescent homes, surgical aid department, and the interest on the debt on Romsley Hill Sanatorium, there remained a balance of £27,500 to be distributed among the hospitals. This distribution was arranged as follows:—General Hospital £9000, Queen's Hospital £6000, General Dispensary £2250, Children's Hospital £2250, Women's Hospital £1650, Eye Hospital £950, Orthopædic Hospital £600, Skin and Urinary Hospital £650, Jaffray Suburban Hospital £750, District Nursing Society £500. Sums varying from £15 to £450 were distributed to 22 other hospitals and nursing associations.

LITERARY INTELLIGENCE.—Mr. Henry Kimpton announces the forthcoming publication of the following books: X Rays and Radium in the Treatment of Diseases of the Skin, by George Miller MacKee, M.D.; Diseases of the Skin, by Richard L. Sutton, M.D., fourth edition, revised and enlarged; Psycho-Analysis in the Service of Education: being an Introduction to Psycho-Analysis, by Dr. Oskar Pfister, authorised translation; How to Become an Efficient Athlete, by John B. McDougall, M.D., M.R.C.P.—Messrs. J. and A. Churchill announce the forthcoming publication of a new book on Nerve Exhaustion, by Sir Maurice Craig, C.B.E., M.D., F.R.C.P.—Messrs. William Heinemann announce the forthcoming publication of the following books: The Practitioner's Manual of Gynæcology, by Dr. A. C. Magian. History of Electrotherapy, by Dr. Hector A. Colwell. Rickets, by Dr. J. Lawson Dick. Influenza: Essays by several Authors, edited by Dr. F. G. Crookshank. Dosage Tables for Deep Therapy, by Dr. Friedrich Voltz; edited and with a preface by Dr. Reginald Morton.

SUNDERLAND ROYAL INFIRMARY: NEW ORTHOPÆDIC DEPARTMENT.—On Nov. 19th the Richardson pavilion was formally opened at this institution to house the orthopædic department. The paid medical officer in charge has a staff of assistants (male and female) trained and certificated in massage, medical electricity, and remedial, including gymnastic, exercises. He is also in charge of the X ray department. The plan of the one-storied brick building was designed by Mr. W. Robinson, senior honorary surgeon, and the architects, Messrs. W. and F. Milburn. The building includes a waiting room, cloak rooms, an office, a medical officer's consulting and examination room, dressing cubicles, rest room, a large room for massage, electrical treatments, radiant heat and light beds, and accommodation for remedial and gymnastic exercises. There are four bathrooms, one for whirlpool and contrast baths, another for Plombières treatment, a third with long baths, aerated and medicated, and an Aix douche, and a fourth for Vichy and spray baths. There is also a room with arm and leg paraffin wax baths, and a heated linen room. It will be seen that the department is also a completely equipped hydropathic installation. The cost of the building and equipment was nearly £9000.

POUND FOR POUND BASIS OF HOSPITAL ASSISTANCE.—At a meeting of the president and general council of King Edward's Hospital Fund for London, held on Nov. 9th, a resolution was passed protesting against the condition, attached by the Treasury to the temporary assistance voted by Parliament to voluntary hospitals, requiring that fresh money shall be raised pound for pound with the Government grants, on the ground that it will lead to great difficulties, and probably to great injustice. This resolution was forwarded through the Voluntary Hospitals Commission to the Chancellor of the Exchequer, who has replied that the stipulation that the Government grant of £500,000 should be administered on a pound for pound basis is absolutely fundamental, and, furthermore, that the £500,000 grant is the limit of Government assistance to the voluntary hospitals.

THE LATE DR. W. M. HUNTER.—William Munn Hunter, who died at the age of 94, on Nov. 10th, at his home in Eckington, was educated at Paisley Grammar School and at Glasgow University, where he graduated M.D., Ch.B. in the year 1862. After acting as ship surgeon, when he suffered shipwreck off the coast of Newfoundland, he entered upon general practice at Eckington and covered a large area on that side of Sheffield, retiring only a few years ago. Of his 11 children, nine are living.

RYE, WINCHELSEA, AND DISTRICT WAR MEMORIAL COTTAGE HOSPITAL.—Princess Louise, Duchess of Argyll, visited Rye on Nov. 15th and opened this hospital, which has been erected just outside the Rye borough boundary at a cost of about £18,000. The building of the hospital has been made possible mainly through the generosity of Lady McIlwraith, while a total of £25,000 has been collected towards this object. The hospital provides 12 public beds and two private wards, the whole being equipped with all the latest appliances.

SOCIETY OF M.O.H.'S: SCHOOL MEDICAL GROUP.—At a meeting of this Group held in London on Nov. 19th, Dr. J. W. Fraser, of Hull, being in the chair, a resolution was passed as follows: "That the Minister of Health should undertake all the powers and duties now delegated to the Board of Education with respect to medical inspection and treatment of children and young persons as was originally intended and as was the expressed wish of Parliament during the passage of the Ministry of Health Act, 1919." All those present were in favour of bringing such a vital health service into organic relation to other health services, such as infant welfare. It was also resolved, in view of the fact that more than 75 per cent. of absence from school is due (or alleged to be due) to ill-health, to ask the Ministry of Health to encourage the policy of appointing nurses as school attendance officers and more effectively to supervise the health of ailing children. The next Group meeting will be held in Birmingham in January or February.

THE LATE DR. JAMES D. WYNESS.—The death took place at his residence, 1, West Craibstone-street, Aberdeen, on Nov. 24th, of Dr. James Davidson Wyness, one of the best known general practitioners in Aberdeen. Dr. Wyness, who was 76 years of age, was the son of Mr. Alexander W. Wyness of Inverurie, and was born there in 1845. He studied at Aberdeen University, where he graduated M.B., C.M. in 1872 and M.D. in 1874. He commenced practice in Schoolhill, from there he moved to Union-street, and later to West Craibstone-street. He had a very large general practice; his was a striking personality, and his kindliness made him exceedingly popular with all his patients. In 1903 Dr. Wyness acquired the estate of Teuchar and Castlehill, near the village of Cuminestown, some five or six miles from Turriff, and latterly spent several weeks there every year. Dr. Wyness was a widower, and is survived by a daughter, his only child.

TYPHOID AT BOLTON-ON-DEARNE.—The Hemsworth Joint Hospital Board, who have already received 13 typhoid cases from Bolton-on-Dearne (West Riding of Yorkshire), have agreed, upon request from the West Riding County Council, to hold 10 beds in readiness for the reception of any small-pox cases arising during the period of the epidemic in the areas normally served by the various small-pox hospitals temporarily in use for typhoid cases. The latter are the small-pox hospitals of the Kendray Joint Hospital Committee at Lund Wood, of the Doncaster and Mexborough Joint Hospital Board at Conisbrough, and of the Wath, Swinton, and District Joint Hospital Board at Hoober. Dr. J. R. Kaye, county medical officer, believes the epidemic to be subsiding, although primary cases are still appearing. A polluted well in High-street, Bolton-on-Dearne, has been sealed and shut off. Three patients died during the week ending Nov. 19th, bringing the total deaths up to 13; there have been 170 cases reported in this outbreak, distinct from the 52 cases during July and August.

LIBRARY

ON SOME
HEART PROBLEMS.

Delivered before the Hunterian Society on Oct. 26th, 1921,

BY ERNEST H. STARLING, C.M.G., M.D. LOND.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY COLLEGE, LONDON.

IN this paper I propose to discuss some questions, connected with the behaviour of the heart in disease of this organ, which have interested me ever since I was house physician. At that time the account given by Cohnheim, based on an experimental study of the problem, was insufficient to explain the various phenomena observed in the wards. My earliest work, therefore, when I obtained the run of a laboratory, was on the heart, and though I have diverged into other fields of investigation, the questions which intrigued me at that time have always retained their fascination, so that I have returned again and again to their investigation. I cannot even now claim to have cleared up the questions which seemed so difficult to answer, and this evening I can only deal with a few of the points which have been eliminated by the investigations of the last 30 years.

THE MARGIN OF ADAPTATION.

Why the heart fails, and how it fails, are problems which must come before us in every disease, not only in those primarily affecting this organ itself; since, in the end, death is due to failure of the circulation, and we mark the point of its occurrence by the moment at which the heart ceases to beat. In heart disease we have a condition in which cardiac inadequacy may continue for a long time. This inadequacy may mean simply a diminution of the margin of response, so that life may continue more or less normal so long as all effort or other condition is avoided, which would throw increased strain on the heart. In nearly every function of the body in the healthy individual there is a margin of adaptation of about 1000 per cent.—i.e., the organ can, working at its utmost, perform ten times as much work, chemical or physical, as is demanded of it during a condition of rest. If this margin is diminished to 500 or 300 per cent., we may speak of a cardiac inadequacy, although, leading a sheltered existence, the individual may remain healthy and all his functions may go on unimpaired. But it is when the margin is diminished below this point, or when it is impossible to preserve an individual from such shocks and strains as call up more than this margin of adaptation, that we get a condition of cardiac insufficiency which we may speak of as heart disease. This insufficiency may be due to gross lesions of the valves, so that the pump is leaky and more work is demanded of it to maintain the normal flow, but in almost every case there is also some disorder of the muscular tissue itself. This disorder may be localised in one part of the heart or may affect the whole musculature. We know that the function of the heart is to pump blood from the venous side, where it enters at a low pressure, into the arteries, and to maintain in the latter a pressure sufficient to provide blood for all parts of the body in proportion to their working requirements. The fraction of the total output of the heart which goes to each tissue is regulated chiefly by the vaso-motor system, though it is also affected by chemical changes in the tissues themselves. As a rule, when one organ or set of organs is working, blood for its needs is supplied at the expense of other parts of the body. Thus hard exercise is accompanied by a diminished flow to the alimentary canal, and when the alimentary canal is flushed with blood, the muscles are not capable of attaining their full activity. To every part of the body the supply of blood is a constantly varying quantity.

BLOOD SUPPLY OF THE BRAIN.

There is, however, one organ which can never go short, however much other tissues may cry out for blood, and that is the brain, the master-tissue of the body, on whose functioning depends the continued existence of all other parts. It has not been possible to prove the existence of a vaso-motor nerve supply to the vessels of the brain, nor is such a supply necessary, since this organ itself controls the blood flow through all the rest of the body and will rob every other part, if necessary, to maintain the flow through itself. The circulation through the brain is therefore dependent almost entirely on the maintenance of the normal blood pressure in the carotid and vertebral arteries. This pressure cannot be diminished without affecting the functions of the master-organ, and we may be certain that every other organ may suffer, including the heart itself, before the brain will allow the arterial blood pressure to drop below the limit at which it can receive a supply of oxygen adequate for its needs. Thus when there is loss of blood, there is a constriction, through the vaso-motor centre, of all the vessels of the body, cutting off blood supply to the skin, intestines, and muscles. There is a lowering of the venous pressure, the heart beats more quickly so that as much as possible of the blood may be passed into the carotid artery to maintain here a normal arterial pressure. If the flow of blood or the supply of oxygen to the brain is diminished, as by ligature of the carotids or by cutting off the supply of oxygen to the lungs, there is again universal vascular constriction so as to raise the pressure in the circle of Willis and vertebral arteries, and to make up by increased velocity of blood for its diminished oxygen content. The same vaso-constriction follows local anæmia of the vaso-motor centre in the brain, such as may be produced by a rise in intracranial pressure.

DIMINISHED OUTPUT OF THE HEART AN ESSENTIAL FACTOR.

Cohnheim, in his investigation of heart failure, argued that any inadequacy of the heart pump must cause a fall of arterial pressure and a rise of venous pressure on account of the diminished output, and was confirmed in his conclusions by experiments in which he tried to imitate the conditions in failure of compensation by gradually filling up the pericardium with fluid, so as to hinder more and more the diastolic expansion of the heart. These experiments, however, put us on a false track. I have already pointed out that in the intact animal the last factor in the circulation to suffer must be the general arterial pressure, since it is on this that depends the flow through the brain. It is surprising how many years we had to wait after Cohnheim's investigation for any actual determination of the blood pressures in heart disease, and I believe the first of this kind were those carried out by my brother, H. J. Starling, in 1906. He pointed out that in no case of ordinary heart disease is the arterial blood pressure found below the normal, though in a considerable number the pressure may be above normal. This is especially the case if the condition is attended with cyanosis, so that the vaso-motor centre is in a partial condition of asphyxia. In general conditions, where for some reason there was a high blood pressure before the onset of cardiac inadequacy, this high blood pressure continues. There is, however, one physical factor in the circulation which is defective. In spite of the normal or high arterial pressure there are very often cyanosis without any corresponding defect in the entry of air to the alveoli, distended veins, and signs of inadequate circulation through all parts of the body except the brain itself. Direct measurement has shown that there is in fact a defective circulation, that the heart at each beat and in each unit of time is putting out less blood than normally. The essential factor, therefore, in heart disease is diminished output of the heart.

Can we form any idea as to how this state of things is brought about? We shall be helped to its under-

Bury St. Edmunds, West Suffolk General Hospital.—Res. H.S. £200.
Cambridge, Addenbrooke's Hospital.—H.P. £130.
Cape Town University.—Technical Asst. in Surgery. £350.

West London Hospital, Hammersmith-road.—Two H.P.'s and one H.S. Each £100.

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, 1906, for County Court Circuit No. 4 (Lancaster County Courts). Applications should reach the Private Secretary, Home Office, not later than Dec. 11th

Births, Marriages, and Deaths.

BIRTHS.

LOWMAN.—On Nov. 23rd, at "Pencarrow," Enfield, the wife of Rupert R. Plowman, of Calcutta, of a daughter.

YWELL.—On Nov. 23rd, at Paget House, S.W., the wife of Dr. Percy Dodd Pywell, of a daughter.

OSS.—On Nov. 27th, at Worcester House, Sutton, Surrey, the wife of J. N. MacBean Ross, M.C., M.D., F.R.C.S., of a son.

COTT.—On Oct. 13th, 1921, at 8 R.A. Lines, Meerut, India, the wife of Major T. H. Scott, D.S.O., M.C., R.A.M.C., of a son.

ILSON.—On Nov. 27th, at Harley-street, W., the wife of Dr. S. A. Kinnier Wilson, of a son.

MARRIAGES.

ORWARD—MIDDLEMISS.—On Nov. 22nd, at St. Cuthbert's, Earl's Court, Dr. Ernest Lionel Forward, M.R.C.S. Eng., L.R.C.P. Lond., to Aileen Frances, only daughter of C. S. Middlemiss, C.I.E., F.R.S., Srinagar, Kashmir, India, and Mrs. Middlemiss, Crowborough.

USSELL—MCKEAN.—On Nov. 9th, at Colombo, Captain Wm. Russell, M.C., R.A.M.C., to Marjorie Doris Clive, younger daughter of George A. V. and Mrs. McKean (formerly of Manchester and Newcastle-on-Tyne).

DEATHS.

ORBIN.—On Nov. 24th, at his residence, Trevenen, Beech-road, Stockport, Herbert Ernest Corbin, B.Sc. Lond., D.P.H., Medical Officer of Health of the County Borough of Stockport, aged 49 years.

LISTON.—On Nov. 20th, at St. Edmund's, Felixstowe, Colonel George Sampson Elliston, C.B., V.D., M.R.C.S., Knight of Grace of the Order of St. John of Jerusalem, in his 78th year.

TCHFIELD.—On Nov. 24th, at 61, Arragon-road, Twickenham, Henry Robert Campbell Litchfield, L.R.C.P. Lond., M.R.C.S. Eng.

NIS.—At Karachi, India, on Oct. 18th, 1921, after a long illness, Sadie Geneviève, the dearly-loved wife of H. Carey Venis, B.A., L.R.C.P., L.R.C.S., D.P.H., Medical Officer of Health, Port of Karachi.

B.—*A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.*

Notes, Short Comments, and Answers to Correspondents.

EGYPT AND THE SOUDAN: HEALTH AND SANITATION.

I.—EGYPT.

A REPORT by Field-Marshal Lord Allenby, His Majesty's High Commissioner, on the affairs of Egypt and the Soudan for the year 1920, includes several references to medical and sanitary matters. The following is a summary of some of the principal points:—

Owing to the fact that the conditions of Government service generally in the various Ministries are at present under investigation by the "Cadre Commission," no material progress has been made in the reorganisation of the health services of the country on the lines recommended by the Government Commission which was appointed in 1918 to advise on this subject. The creation of a post of Under-Secretary of State for Health in June of last year has been of some advantage to the administration in so far as it has placed the head of the service in the position of being able to act with greater effect in all matters affecting the health interests of the country, but the directorate is still needlessly overloaded with many matters of trivial detail which will be difficult to get rid of until the four main branches of the administration are put in the position of autonomous services dealing directly with other Government administrations as regards their own work, whilst the functions of the controlling authority in its relation to them are largely confined merely to such intervention as is necessary for the coördination of their efforts. With the creation of the new post of Under-Secretary of State there occurred certain changes in the positions of the higher personnel. The director-general became Under-Secretary of State, the deputy director-general was made director-general, whilst the post of deputy director-general was suppressed and a new post of inspector-general was created, to which was appointed one of the senior Egyptian divisional inspectors, Dr. Ahmed Bey Tewfik. The dissatisfaction with the conditions of service in the public health administration continues, but the difficulties of recruiting for the service were somewhat eased during 1920 by the hope that some improvement might result from the findings of the Cadre Commission.

Special Legislation.

During the past year two questions urgently called for fresh legislation. The requirements of the first of these were met by the introduction of a new law giving greater powers of dealing with unqualified dental practice, which had gradually become a serious public danger. The penalties under the old law afforded an insufficient deterrent to a gradually increasing number of ignorant persons who found in the practice of dentistry a lucrative source of gain, and in February the new law was promulgated. In order to draw some distinction in favour of those unqualified practitioners, who by long practice had acquired some empirical knowledge of the art, provision was made for the grant of a modified form of permit to those who had been in continuous practice as dentists for ten years or more and who could pass a special examination. Of 218 candidates admitted to the technical examination 193 satisfied the examiners. The second question which called for special legislation was first brought to notice in the summer of 1919 when it was reported to the department that a soldier of the British Army had contracted anthrax by using an infected shaving brush, which was found to be one of a consignment recently imported from Japan. On May 29th a law was promulgated forbidding the admission of any shaving brushes into the country unless accompanied by certificates of disinfection from the competent authority in the country of manufacture. With the cessation of hostilities and the greater facility for obtaining labour, the work of filling in or draining those ponds of stagnant water and marshes which constituted a danger to public health was again actively taken up and has progressed considerably. Twenty-nine Government-owned birkas were filled in, with an aggregate area of 75,179 square metres.

Prostitution.—Medico-Legal Examinations.

The number of prostitutes registered in Egypt was 5836. 173,931 examinations were made, in the course of which 1085 women were found suffering from syphilis, 4306 from gonorrhœa, and 959 from other diseases. During the year 7860 prostitutes actually received treatment in Government hospitals, 1425 of these being for syphilis, 5729 for gonorrhœa, and 719 for other diseases.

During 1920 60,405 examinations of injured persons were carried out by the medical officers of the Public Health Department. Of these, 12,554 were accidental injuries, such an extent by increased dilatation that it tears its own structure in its effort to cope with the increased load thrown upon it, and post mortem one finds the heart muscle studded with small hæmorrhages. In the body this over-distension is prevented by the pericardium, and possibly in some hearts the physiological process of adaptation by dilatation may be limited by the fibrous character of the myocardium. But in each case the cardiac inadequacy will reveal itself by a diminished output, to which the central nervous system, in its selfish activity, will respond by shutting off the blood supply to the various organs of the body, so that the greater part of the output can be diverted to the brain and an adequate pressure maintained in the carotid and vertebral arteries. In this condition the main arterial trunks will be normally distended. The peripheral vessels, capillaries, and veins will be depleted of blood, as shown by the pallor of the skin, while there will be a certain amount of distension of the auricles and great veins near the heart.

But the process does not end here. The lowered capillary pressure and diminished flow through the tissues at first cause increased absorption of fluid from the tissues, especially from the alimentary canal, associated with diminished urinary secretion. The result of these factors is to increase the amount of fluid in the circulation, causing a condition of hydræmic plethora, which, in the presence of cyanosis and the consequent stimulation of the bone marrow, may be converted into a real plethora, a new formation of red corpuscles keeping pace with the increased volume of the blood flow. The venous system and capillaries thus fill up to their normal pressure, the arterial trunks remaining as full as before. This increased filling of the veins tends to produce a further rise of diastolic pressure, but cannot cause any further dilatation of the heart except by a gradual giving way of the pericardium, and therefore will not evoke any stronger contraction of the cardiac muscle. The increased venous pressure may cause, reflexly, a still further acceleration of the pulse; but it will not be indefinite, since, as Bolton has shown, the veins tend to give to the increased pressure in their interior, so that one finds them distended although the pressure in them is only a few millimetres of water above normal. Under these extreme conditions, too, the rate of the heart will depend not only on the reflex acceleration through rise of auricular pressure, but to a still larger extent on the central excitation of the cardio-inhibitory or cardio-acceleratory mechanism dependent on the state of the brain itself, fall of blood pressure in the cranium tending to cause acceleration, while other physiological conditions may excite the vagus centre and diminish the rate of the heart, so that it is difficult in any given case to prophesy what will be the resultant rate of the heart.

Even though the heart dilates and quickens, the sparing of this muscle is the office of the central nervous system, and this maintains the arterioles constricted, so that the amount of blood coming into the venous system and into the heart is less than normal, and the heart remains at just that stage of dilatation at which it can empty a diminished amount of blood into the arteries against a normal arterial pressure. As a rule, however, this adaptation affords only an imperfect protection for the diseased organ, since it calls into being other morbid states which have a secondary influence on the heart muscle and tend to make its condition worse. The muscular weakness we may regard as protective, since it is the muscular contractions which are the main factor in determining the inflow of blood into the heart. The diminished flow through the lungs, however, causes deficient oxygenation of the blood, which reacts unfavourably on the functional capacity of the heart muscle. The functions of the alimentary canal are interfered with, thus retarding nutrition; the functions of the kidneys are diminished, so that excretion of waste products is imperfectly carried out. The whole venous and capillary system gradually fills up with stagnant badly oxygenated blood, and as a result there is deficient nutrition of the capillary wall with increased exudation of lymph and the production of dropsy in all the dependent parts of the body. In the upright position it must be remembered that the main factor in maintaining the venous flow towards the heart consists of the contractions of the voluntary muscles, so that the capillary pressure normally in the feet is not higher than that in the hand. If these movements are absent, the capillary pressure rises in all dependent parts by the amount of hydrostatic pressure represented by the height of the heart above the part; this fact in itself is sufficient to account for the gradually increased transudation of fluid.

Thus the law of the heart, which expresses so perfect an adaptation of this organ under healthy conditions and with intact muscle fibre, is limited under extreme conditions in the normal individual and under ordinary conditions in the diseased individual by three factors. Two of these consist in a mechanical limitation of the dilatation which may evoke increased energy of contraction, and are in the first place the pericardium, and in the second place (in disease) inextensibility of the myocardium in consequence of development of fibrous and scar tissue in its interstices. In the third place, a continuous and indefinite rise of diastolic pressure is prevented by the gradual dilatation of the large veins to accommodate the excess of fluid which remains in them, and the diminished rate of flow of blood through the capillaries into the venous system.

I cannot pretend to have explained all the phenomena of uncompensated heart disease by the action of the few factors which I have discussed. I have shown that a consideration of the isolated heart-lung enables us to understand how heart failure, however brought about, must lead to a limitation of output, but it is hardly conceivable that the heart in situ, unable to respond to the demands made upon it, does not itself invoke the interaction of the central nervous system, which may be used either to increase the response of the heart muscle, as certainly occurs in the healthy individual, or possibly to save the muscle at the expense of other organs of the body, subject only to the demands of the brain itself, when the heart is in danger of failing through excessive fatigue. It is possible, too, that other factors, such as retarded rate of relaxation, may serve to diminish the inflow into the tired heart. But of these factors we have very little knowledge, and the part to be assigned to each requires a profounder clinical knowledge of the failing heart than I can pretend to possess.

Treatment of Failure of Compensation.

Although we cannot claim by our inquiry to have obtained a clear image of all the factors concerned in producing the clinical signs of failure of compensation, we are enabled to see the physiological reason for the efficacy of various measures employed in its treatment.

1. Most important is rest, which not only diminishes the demands on the heart from the arterial side, but by removing the main cause for the return of the blood to the heart enormously decreases the inflow into this organ; and it is inflow which in the healthy heart determines output.
2. The value of oxygen, when there is any cyanosis, is explained by its action in diminishing the blood pressure necessary to drive a sufficient amount of blood through the brain, the relaxation of arterioles, and the improved supply to the vital organs of the body, and the direct effect of a proper supply of oxygen in improving the contraction and aiding the reintegration and recovery from fatigue of the heart muscle.
3. The plethora attending failure of compensation is a reaction on the part of the organism as a whole, not on the part of the heart, and does not assist this latter organ. It may, in fact, be harmful when the heart is beginning to recover under the influence of the other modes of treatment just mentioned. One can therefore understand the beneficial effects of bleeding as a preliminary measure in certain cases of

EUGENICS IN SWEDEN.

In May last the Swedish Riksdag decided by an overwhelming majority to provide funds for the foundation of an institute for the study of eugenics. It is claimed that this is the first instance of a national governing body giving tangible proof of its conviction that the science of eugenics has at least a putative practical value, and that the State must help as well as exploit the researches of race-hygienists. The appointment of Prof. Herman Lundborg as Director of this State Institute for the study of race-biology augurs well for the future. Important papers which he has already published on hereditary factors in tuberculosis are a guarantee that essential questions will not be neglected at the institute under his control.

A MEDICAL ART CALENDAR.

The fourth annual issue is announced of the well-known illustrated Medical Art Calendar issued by Mr. J. Philip Kruseman at The Hague, with text in English and Dutch. The present calendar delineates the alchemist, the barber-surgeon, and the dentist in their workshops rather than the family physician, and may be regarded as caricature more than portraiture. But the numerous artists of the Dutch school whose works are reproduced give evidence of their customary insight into character, and the collection has considerable archæological interest. The ways and manners of some of the characters portrayed are still to be observed among the unqualified or unregistered practitioners of the healing art. The price of the calendar is 6s. post free.

DREAM FAIRIES.

Dr. T. Wilson Parry, whose modest excursions into verse belie the popular idea that doctor and materialist are synonymous terms, has, in his book entitled Dream Fairies (London: Simpkin, Marshall, Hamilton, Kent and Co., 1921, pp. 34, 2s. 6d.), some pretty conceits about flowers and fairies. His nine themes and the dedication—

> To every child whose spirit wild
> Hears beckonings from the brook—

are illustrated by a series of ten designs from the pencil of Mr. Gerald Aylmer, whose imagination and dexterous pen have caught the message of the verses while displaying a keen appreciation of floral beauty. One of the pieces, "The Prescription," has already appeared in *St. George's Hospital Gazette*, and a quotation from it will show the spirit in which Dr. Parry writes:—

> R A nettle-sting,
> Lustre from a lace-fly wing,
> Glitter from a night owl's eye,
> Wing-down from a butterfly,
> Sheen from a grasshopper's skin,
> Flashings from a troutlet's fin,
> Glimmer from a glow-worm's light,
> Glint from a kingfisher's flight,
> Add the blush of one wild rose,
> Several dew-drops interpose,
> Pound them in an acorn-cup,
> Then, dear fairy, drink it up.

The thin quarto is in a dainty cover and the print is bold. It would make a welcome present for a child at Christmastide and it should equally appeal to many grown-ups.

A COMBINED BIRTH CONTROL AND WELFARE CENTRE.

The centre, which began its career at 153a, East-street, Walworth, London, S.E. 17, on Nov. 9th, was open to members of the press on Nov. 24th. The centre is being conducted under the auspices of the Malthusian League, its object being to give definite instruction in regard to birth control, as well as the advice usually given at infant welfare centres. There is a nurse in attendance daily, but enquirers about birth control are directed to attend the doctor's special weekly consultation. It is not taken for granted that those attending wish for information about birth control unless they ask for it, but such information would apparently be given as willingly to a young, newly-married woman as to one who already had a large family, though some preliminary inquiries are always insisted upon. There does not seem to be any promise required that the instruction will not be handed on to others. The centre is still in its infancy, but later on visits will be paid to the homes in order that the conditions in individual cases may be ascertained. Structurally the premises appear adequate. On the ground floor there is an unfurnished room in which prams may be left, also a secretary's room and a doctor's consulting room; upstairs, the waiting room, stretching the full length of the house, has been made attractive with good picture posters and brightly-coloured washing cushion seats. The centre is not connected with any municipal or local authority, but is run entirely as a voluntary concern, advertised by means of open-air lectures in South London, and by the distribution of educational leaflets and forms of application.

VENEREAL DISEASE IN AUSTRALIA.

An association is to be formed for the prevention of venereal disease in Victoria. It will consist of laymen and medical practitioners, and its activities will be mainly educative, Sir James Barrett being the moving spirit in the new organisation. A somewhat similar body already exists in New South Wales. In Western Australia the Government proposes to abolish the compulsory notification provisions of the existing Venereal Disease Act in that State. The general experience of notification in those Australian States which have special venereal disease legislation has been disappointing; it is quite certain comparatively few females are notified. Compulsory treatment does not appear very satisfactory, and there is great divergence of opinion as to the value of certification of cure.

THE SCHOOL CHILD'S ENVIRONMENT.

Some indication of the effect of environment upon the physical condition of children of school age arises from comparative examinations at the Allcock-street and Bournville elementary schools made by Dr. J. B. Lowe, assistant school medical officer of Birmingham. The former is an old building, situated in one of the most congested areas of Birmingham, a district full of back-to-back and tenement houses; while the latter is a modern building in an industrial suburb. The allowance of cubic and floor space per boy is, however, the same, and it is stated that there are no marked differences in the ventilation, heating, or sanitary conditions of the two schools. The examination consisted of an ordinary medical inspection and the recording of physical measurements. The differences shown were as follows: Allcock-street (out of 118 scholars): Above normal, 6 per cent.; below normal, 41·5 per cent. Bournville (out of 106 scholars): Above normal, 17 per cent.; below normal, 19 per cent.

AN INSTITUTE OF APPLIED PESTOLOGY.

At the London Pavilion, Shaftesbury-avenue, on Nov. 24th a meeting was held with the object of inaugurating an Institute of Applied Pestology. Dr. Nathan Raw, M.P., presided, and those present included Lord Aberconway and representatives of the medical and other scientific professions. Mr. Alfred E. Moore, of the Inc. Vermin Repression Society, delivered a short address in which he pointed out that the new Institute sought to coördinate efforts in the extermination of all pests, not rats alone. The effects of the Rats and Mice Act, recently passed, were nullified by allowing rubbish dumps to form suitable breeding grounds for myriads of mice. Men in universities and hospitals were spending their lives in seeking to find remedies for pest-borne disease at a remuneration often not greater than a dustman's wage. The Institute would endeavour to remedy this state of things and to assist manufacturers in exterminating the pests which ravaged their stocks and raw material. By articles in the press, by the exhibition of films, and in other ways, it was hoped to educate the public. An executive committee was then constituted with Mr. Moore as chairman; Mr. J. E. Pryde-Hughes and Mr. J. L. Hayden, joint hon. secretaries; Prof. F. Hobday, F.R.C.V.S., and Col. S. J. M. Auld, D.Sc., were among those nominated as vice-presidents. The subscription was fixed at 1 guinea for Fellows, 5 guineas for Members, and half a guinea for Associates. The meeting closed with an exhibition of films showing how rats enter and leave ships, warehouses, and wharves, how they destroy live stock, materials, and property and defile food, and the methods for destruction of rats recommended by the Ministry of Agriculture and the Vermin Repression Society. The address of the Institute is 168, Fleet-street, London, E.C.

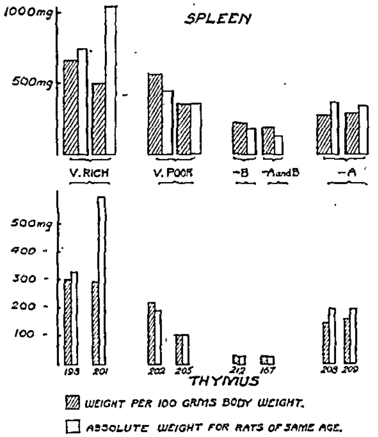
animal to as low as 1200 has been observed. The polymorphonuclear leucocytes are not affected to the same extent. As a result a differential count gives figures in which the proportions are completely changed. In a normal rat the polymorphonuclear leucocytes constitute about 30 per cent. of the total leucocytes, representing in absolute figures about 2600 cells. As the condition resulting from the deficiency of vitamins progresses the relative proportion of the polymorphs increases, so that in the later stages they may equal in number the lymphocytes and even exceed them (see Fig. 2, rats 161 and 167).

Comparative Effects of Deficiency of A- and B-Vitamins.

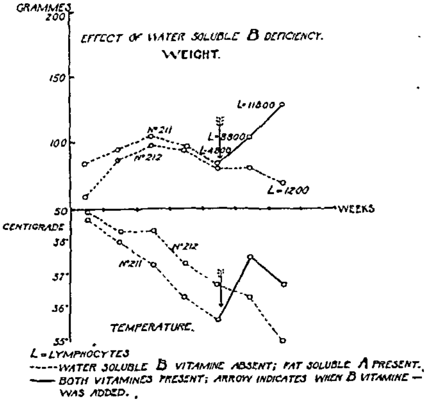
When a diet deficient in B-vitamin but containing vitamin A is given, the same general results follow in rats as when both vitamins are absent (see Fig. 3, rats 211 and 212). There is the same initial cessation of growth, followed by a decline in weight and a gradual fall of the temperature. In the final stages of the water-soluble B deficiency the animal presents the same condition of emaciation. This identity of the condition for the specific water-soluble B deficiency with that for the complete vitamin deficiency is

FIG. 1.



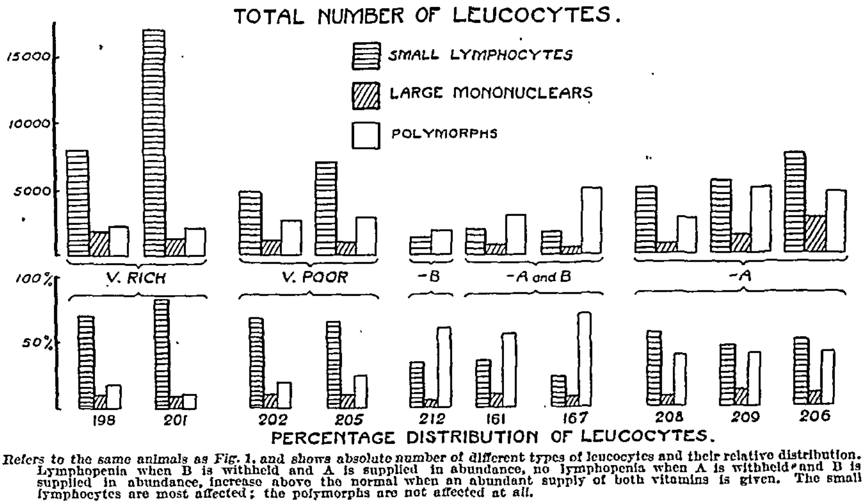
Shows weights of spleen and thymus altering with changes in the diet. Note that the vitamin-rich diet is an artificial diet, while the vitamin-poor diet is a natural diet—namely, the laboratory diet of bread and water, maize and rice referred to in the text, which is, however, adequate to maintain the animals in good health. The weights are given both calculated per 100 g. of body weight (shaded), and in absolute figures for rats of equal age (not shaded). Atrophy as the result of withholding vitamin B, no atrophy when vitamin A is withheld. Great increase in weight when an abundant supply of vitamins is given.

FIG. 3.



Curves of weights and of temperatures and number of lymphocyte counts of two rats on a diet free from vitamin B alone, but containing an abundant supply of vitamin A. Effect on weight, temperature, and number of lymphocytes of adding the deficient vitamin to the diet of one rat (No. 211).

FIG. 2.



Refers to the same animals as Fig. 1, and shows absolute number of different types of leucocytes and their relative distribution. Lymphopenia when B is withheld and A is supplied in abundance, no lymphopenia when A is withheld and B is supplied in abundance, increase above the normal when an abundant supply of both vitamins is given. The small lymphocytes are most affected; the polymorphs are not affected at all.

standing by a study of the isolated heart, provided that we remember that it is the isolated heart that we are studying and do not imagine that the results obtained thereby will suffice by themselves to explain the phenomena met with in the complex vascular system with its multifarious relationships, nervous and otherwise, in the body. In physiology we analyse each complex function into its constituent parts in order that we may synthesise them again later and understand the function as a whole. Physiology may become a dangerous guide in clinical medicine if we forget this process of synthesis and try to explain any complex morbid condition with our eyes directed only on one or two of the factors involved.

ACTION OF THE ISOLATED HEART.

With this caution in mind, we may learn something from the behaviour of the isolated heart. We can make a preparation of the mammalian heart and lungs entirely separated from the rest of the body, so that the heart is cut off from all nervous influences and is simply a muscular pump causing a flow of blood through an elastic system of tubes. In this case the only variable factor is the muscular wall of the heart. All the other conditions—the amount of blood entering the heart, the resistance to the flow of blood from the heart, the arterial pressure, the temperature at which the heart works—are directly subject to our control, and can, if we so desire, be maintained constant. And we can measure the pressures in any of the cavities of the heart, the total amount of blood put out by the heart, as well as changes in the systolic and diastolic volume of this organ. In studying the heart under these conditions, we are at once struck by the perfection of its mechanism. The heart of a dog, released from the vagus control to which it is normally subjected in the body, beats at about 140 per minute. The rate of this beat is unaltered by any mechanical conditions, and is simply a function of the temperature of the pace-maker in the right auricle, and therefore can be modified at will by altering the temperature of the blood entering the heart. If we increase the amount of blood entering the heart by raising the venous reservoir or by relaxing the screw clip on the wide tube passing to the right auricle, the heart sends out a correspondingly increased amount of blood into the pulmonary artery and into the aorta. If we maintain the inflow constant and alter the arterial resistance, we find that the heart still maintains its output unchanged, although the arterial pressure, and therewith the work thrown on the heart, may be increased from 50 mm. Hg to 250 mm. Hg. There is, of course, a limit to this power of adaptation possessed by the heart. If either the inflow or the arterial resistance is increased too much, the blood may accumulate in the heart cavities, the diastolic pressure rises, and the output falls off. This limit depends in the first place on the pericardium, and may be raised by opening the pericardium, when the distended heart is found to give a maximum output greater than when it is confined by the pericardium. The enormous work at the highest limits of capacity of the heart is only performed at the expense of the heart muscle, and one finds hæmorrhages in the heart muscle due to rupture of its fibres after it has been made to work at this maximum power during 10 or 20 minutes.

MECHANISM OF ADAPTATION.

I have shown that this power of adaptation possessed by the isolated heart is determined by a very simple law—namely, the relationship between the length of the heart muscle and the force of its contraction. In any given heart, the greater the length of its muscle—i.e., the greater the dilatation of the heart—the stronger is the contraction. Thus if the work presented to the heart is suddenly increased, the heart fails for a time and therefore gradually dilates. But with each dilatation its contraction becomes stronger, so that finally the heart is putting out as much blood as before but with a greater systolic and diastolic volume. With a constant inflow the physiological condition of the heart, its contractile power, is measured by its diastolic size. A heart in good condition contracts strongly with only a small diastolic distension, so that it practically empties itself of blood at each systole. As its physiological condition deteriorates, its fibres have to be longer to exert the same force during contraction. We therefore find that the heart dilates, and though it is sending out at each beat as much blood as before, there is a considerable amount of residual blood in the heart at the end of each contraction. We speak of the heart in the first condition as one with "good tone," and the second condition as "bad tone." Thus, if we keep the mechanical conditions of an experiment on the isolated heart constant, the heart will gradually get larger as it becomes tired, but there will be no signs of failure of the circulation, the output and the arterial pressure remaining constant.

Let us suppose that a well-trained athlete starts to run. Even before he starts there will be a central preparation for the exercise, which will be shown by a quickened respiration and a rise of blood pressure. As soon as he begins his course the pumping movements of the muscles of limbs and respiration will largely increase the inflow of blood into the right heart. The heart will react to this in two ways. In the first place it will dilate, and by this means will give a stronger contraction and send out on the arterial side the whole of the blood that it receives. Other things being equal, the increased diastolic filling will cause some rise of pressure on the venous side of the heart, and as a result there will be reflex inhibition of the vagus control, with probably some stimulation of the accelerator nerves, and a quickened pulse beat. The heart reacts therefore to exercise by increased output per beat and by increased rate of beat. We find these two factors taking a varying part in the adaptation to exercise in different individuals. In the well-trained man the increased output per beat may be more marked than the rise in pulse-rate. In the untrained individual—i.e., in an individual whose heart has probably a poor tone and a larger residual quantity of blood at the end of each beat—it is the quickening of the pulse-rate which is more evident. Finally, however, the heart may be putting out three times as much blood at each beat and contracting at a rate two and a half times normal, so that the total output per minute may be increased seven or eight times. Since under these conditions there is a somewhat more effective utilisation of the oxygen carried by the blood, the heart is able to supply the ten-fold increase in oxygen which is required by the contracting muscles.

EFFECT OF FATIGUE.

These conditions cannot, however, endure indefinitely; the heart muscle working at eight times its normal rate tires. The phenomena of fatigue can be studied in the heart-lung preparation. Fatigue means diminution of physiological efficiency—i.e., the heart, in order to produce a given rise of pressure at its contraction in its interior, must start from a more dilated condition than when it is fresh. But a heart at its maximum efficiency is dilating at each diastole to the limits set by the indistensible pericardium. It cannot then dilate more during diastole. The effect of fatigue, therefore, is simply to reduce the output of the heart. This may be felt in various ways. If it affects all parts of the heart, the insufficient supply to the muscles causes muscular weakness and incoördination. If it affects chiefly the right side, there may be signs of anoxæmia, such as headache and vomiting, as well as muscular weakness. The man is forced finally to give up running through fatigue, but the fatigue in this case is almost entirely failure of the circulation by failure of the heart. We see therefore that in this muscular fatigue, the output of the heart, though increased above the resting amount, is insufficient for the needs of the body. In the diseased heart, the muscle is inadequate for the normal needs of the body. A healthy heart deprived of its pericardium will react to

(*B*) A consideration of the effects of X radiation upon animals shows that a primary destruction of lymphocytes is followed by disturbances in nutrition identical with those produced by withholding B-vitamin. (*C*) Other evidence on the relationship between the functional activity of the lymphoid tissues and the nutrition of the body. (*D*) A criticism of the prevalent conception that vitamins are essential for the life of every cell.

A. *Effect of a Diet Rich in Vitamins.*—The effect of a diet particularly rich in vitamins has been compared with that of a diet poor in vitamins but containing sufficient to maintain the animals in good health and in a normal condition.

TABLE II.

Diet.	Rat No.	Weight in g.		Final length in cm.*	Weight in mg. of—		Lymphocytes distribution.				
		Initial.	Final.		Spleen.	Thymus.	Total in 1 c.mm.	Small L.	Large L.	Polym.	Eosinoph.
Vitamin-rich	198	40	110	15·5	740	330	9,600	71·5 %	8·5 %	17·5 %	2·5 %
	201	60	210	18·5	1060	690	18,300	83·0 %	6·0 %	11·0 %	0·0 %

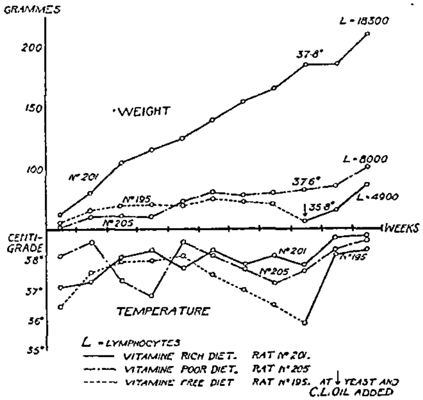
	205	50	100	14·5	360	105	8,000	64·5 %	8·5 %	25·5 %	1·5 %

* Nose to root of tail.

The vitamin-rich diet is an artificial food mixture and onsisted of the vitamin-free standard basal ration (extracted casein, starch, olive oil; salt mixture) to which dried yeast and cod-liver oil had been added. The vitamin-poor diet is a natural diet. It consisted of a diet of bread soaked in water alternating with boiled rice and maize. This has been for years the usual diet of all the rats of the Imperial Cancer Research Fund laboratory. That this diet maintains them in good health is evident from the fact that they breed on the diet and suffer little from intercurrent disease, epidemics being rare. They put on weight and grow, though slowly. Table II. gives a comparison of two young rats kept on this laboratory diet for ten weeks with two rats of equal age kept on the vitamin-rich diet. The latter put on weight and grow in size much more rapidly although the diet is artificial. There is no difference in the temperature, but there is a distinct difference in the development of the lymphoid tissue. The weight of the thymus of rats of equal age is much greater on the vitamin-rich diet; it is heavier even when calculated for 100 g. of body-weight. (See *Fig.* 1.) The spleen also tends to be heavier on the vitamin-rich diet if calculated per 100 g. of body-weight, and is much heavier when the absolute figures, comparing animals of equal age, are considered. (See Fig. 1.) The total number of lymphocytes is also higher on the vitamin-rich diet. (Fig. 2.) In rat 201 (see Fig. 6), which grew most rapidly and reached the weight of 210 g. in ten weeks, while in the same time another rat (No. 205) with the same initial weight, but kept on the laboratory diet, had reached only 110 g., the total number of *lymphocytes gave the exceptionally high figure* of 18,300. That this was not accidental or due to an error was confirmed by another count a few days later, which gave 17,800. It has been noted that rats from the laboratory of the Radium Institute, where a very varied diet is given, grow much more quickly and give lymphocyte counts *decidedly higher. These experiments emphasise the importance of the vitamins.* Not only is a certain minimum necessary for the healthy vegetative and reproductive life of an animal, but if increased beyond this limit the vitamins, in a drug-like action, produce a further effect.

FIG. 6.



Curves of weight and of temperature and number of lymphocytes of three rats kept on an artificial diet rich in vitamins, on a natural diet poor in vitamins, and on a completely vitamin-free diet respectively. Also recovery of rat 195 kept on the vitamin-free diet when vitamins are added again.

We therefore feel justified in concluding that an ample supply of vitamins A and B stimulates the functional activity of lymphoid tissue and that this is associated with more rapid growth and a general improvement of nutrition.

B. *Effects of Exposure to X Rays or Radium.*—A consideration of the effects of exposure to X radiation or to radium has an important bearing on the thesis.

The first change to be observed is a diminution in the number of circulating lymphocytes; so sensitive is this reaction that an amount of radiation insufficient to be detected photographically will cause an appreciable diminution in the number of circulating lymphocytes within an *hour after exposure. Not only do the circulating lymphocytes* disappear from the blood, but moderate exposures will sterilise the whole body of lymphoid cells so that an examination of spleen, thymus, or other lymphoid tissues will reveal a more or less complete absence of these cells. If by means of repeated small doses of radiation this *lymphopænia be kept up, changes subsequently occur in the* animal identical with those resulting from the withholding of B-vitamin. The animal rapidly loses weight, the temperature falls, the testicles present an atrophic condition, adipose tissue disappears, and the animal finally becomes "marasmic" and dies.

The immediate disappearance (within an hour) of circulating lymphocytes following radiation has no decided analogy with the effects of withholding vitamin B; on the other hand, the general and maintained absence of those cells associated with repeated doses of radiation appears to be due to an interference with their production, and a similar want of production is to be observed in the lymphoid tissues of animals starved of vitamin B. In this respect, also, the two effects would seem to have common ground. The regeneration of the lymphoid tissues, which follows the atrophy due to radiation when exposure is discontinued, is strikingly similar to that observed in vitamin experiments when the deficient vitamin B is added to the diet. The spleen, thymus, and other lymphoid tissues increase in size and present abundant production of lymphocytes; the blood content passes from exhibiting a lymphopænia to a lymphocytosis, which may sometimes far exceed the norma limit; and the general condition of the animal then becomes normal. *Fig.* 7 gives the results of an experiment especially designed to illustrate these effects of radiation, which since their discovery 15 years ago,[9 10] have been extensively studied, both in this country and in the United States.[18 19 23 27 33] The observations were made on eight rats, of which four were subjected *intermittently to exposures of radium* over a period of 21 days, while the other four animals were kept as controls. The amount of radiation applied was measured. By the use of screens, and by varying the amount of radium bromide, the exposure to radium was varied on different days. The maximal exposure given at one time was 0·20 rads and was given on the first two days and on the last day. The intermediate exposures were smaller and varied from 0·02 rads to 0·04 rads. The total exposure given over the whole period amounted to 1·25 rads, failure of compensation, as well as the value of diminished salt intake.

4. Another factor of importance in enabling the heart muscle to recover its physiological condition is the circulation through the coronary vessels. In my earlier experiments on the isolated heart-lung preparation I used to put the arterial pressure low, in order—as I thought—to give the heart, under the abnormal conditions of experiment, as little work as possible to do. Many hearts, after the artificial circulation had been established, continued to fail and finally went into delirium or ceased to beat. One day, when the heart was obviously failing, I put up the pressure to 150 mm. Hg, thinking that I should kill the heart outright. Instead of this happening, the heart first dilated widely and beat more forcibly, but as it reacted to the pressure in the arterial system it steadily improved, and both its diastolic and systolic volumes diminished. It continued to beat against this high pressure for hours, so that on all subsequent occasions I have raised the arterial resistance to start with, so that the heart, as soon as it is connected with the artificial system of tubes, has to contract against a high resistance. In my early experiments the arterial pressure had been insufficient to furnish an adequate supply of blood through the coronaries to the heart muscle. As soon as this was supplied by a temporary rise of blood pressure, the heart muscle steadily improved and the heart was able to contract against an abnormally high resistance without undue dilatation, improvement in physiological condition being marked by diminished volume, or as would generally be stated, increased tone of this organ. I am inclined to ascribe the beneficial effects of graduated exercises in heart disease very largely to the improvement of the coronary circulation brought about by the temporary rise of arterial pressure accompanying the exercises. So important is the coronary circulation for the functional capacity of the heart that every medical man should be aware of the manner in which this circulation is regulated. The oxygen usage of the heart is directly proportioned to the work it does, and its oxygen supply must therefore vary within the same limits as its work—i.e., in a healthy heart from 1 to 7 or 10. The most important factor, as is shown by the accompanying table, in determining the amount of blood flowing through the coronary arteries, and therefore the oxygen supply to the heart muscle, is the arterial pressure, so that as the resistance to the heart beat increases, there is a corresponding increase in the flow of blood through the heart muscle. Under extreme conditions of work the flow through the heart muscle may be greater than has been found in any other organ of the body and may amount to 5 c.cm. of blood per minute for every gramme of heart muscle. But the supply of blood and of oxygen is aided by two more circumstances. In the first place, as soon as increased strain is thrown on the heart, or this organ commences to fail, we find an augmented flow through the coronaries out of all proportion to the blood pressure the aorta. This is not due to the accumulation of carbonic acid in the blood and must be determined by the formation of metabolites, of which lactic acid may be one, in the labouring muscle fibres. Moreover, the heart has an astounding power of utilisation of the oxygen in the blood. When an isolated heart is fed with blood from an asphyxiated animal, we find that the heart removes the last traces of oxygen from the blood, so that the blood from the coronary sinus does not contain one-half per cent. of oxygen. The enormous range of adjustment in the coronary circulation characteristic of the healthy heart enables us to form some idea of the evil results which must follow impairment of the power of adjustment, such as may occur in consequence of disease of the coronary arteries themselves. We may see how rapidly such a failure of adjustment may act on the heart muscle by repeating Cohnheim's experiment of ligature of one main branch of the coronaries. This is almost invariably followed, within a period varying from a couple of minutes to half an hour, by fibrillation of the ventricles and death of the animal, and a similar result may occur in man as a result of any unequal derangement in the powers of adjustment possessed by different parts of the coronary system.

ON THE FUNCTION OF THE LYMPHOCYTE AND OF LYMPHOID TISSUE IN NUTRITION,

WITH SPECIAL REFERENCE TO THE VITAMIN PROBLEM.

BY W. CRAMER, D.SC. EDIN., PH.D. BERL., M.R.C.S.;

A. H. DREW, D.SC. LOND.;

AND

J. C. MOTTRAM, M.B. LOND., D.P.H.

(From the Imperial Cancer Research Fund, London, and from the Radium Institute, London.)

WHEN a rat is kept on a diet completely free from vitamins its growth is at first arrested, then its weight declines, its temperature falls, and eventually the animal dies in a state of complete emaciation. The ordinary white adipose tissue has completely disappeared. The glandular adipose tissue—the "brown fat"—is still present; but microscopic examination shows that most of the cells still contain very small droplets of fatty material, which are, however, much smaller than those found in a normal rat, and in some cells may be quite absent. There is a profound atrophy of the lymphoid tissue, which is obvious to the naked eye. This is most striking in the thymus, which is hardly visible. The Peyer's patches, which stand out very clearly in the intestine of a normal rat, are mostly not visible to the naked eye; after careful search a few can be detected here and there. The spleen is shrunk to a narrow ribbon (see Fig. 1, rat 167). The size of the lymphatic glands in the mesentery and in the groin underneath the skin exhibits such variations, even in normal animals, that it is difficult to appreciate differences in size in animals kept on a vitamin-free diet. Microscopic evidence shows that the lymphoid tissues are empty of lymphocytes. Not only is there a diminished production of lymphocytes in the spleen and lymph glands, but the disintegration of lymphocytes in these organs is also diminished as indicated by the infrequent occurrence of phagocytosis and the relative absence of cellular debris. This change in the lymphoid tissue is reflected in the blood. There is a diminution in the total number of lymphocytes; of these, the small lymphocytes are particularly diminished. This diminution may amount to 50 per cent. when the animal begins to show definite signs of suffering from the lack of vitamins, as indicated by its ruffled fur and by fall of temperature to about 36°, instead of 37°–38° given by a normal animal. In the final stages a fall in the number of lymphocytes from the average figure of 8000 per cmm. of the normal feeding, and in which the only lesion found so far has been atrophy of the thymus.[25] We have not been able to find in the literature systematic observations on the condition of the lymphoid tissue generally in this condition. Dr. D. H. Paterson[22] has kindly informed us that in his observa*tions on post-mortem examinations of cases of malnutrition* and marasmus carried out in the Hospital for Sick Children, Great Ormond-street, he has always found an atrophy of the spleen associated with an atrophied thymus, and that the Peyer's patches were so atrophic that they could not readily be made out. We have not been able to find in the literature observations on the lymphocytes in the different *conditions of malnutrition and marasmus.*

D. *Necessity of Vitamins for Individual Cell Life.*—Are vitamins necessary for the life of the individual cell or for the life of the animal as a whole? The fundamental assumption has been made—and is now generally accepted—that every living animal cell requires *not only foodstuffs but also vitamins:* life cannot exist without vitamins. That is, in fact, the definition of vitamins.

MacCarrison[17] suggests as an explanation the analogy that "vitamins are as the spark which ignites the fuel mixture of a petrol-driven engine, liberating its energy. The spark is of no use without the fuel, nor the fuel without the spark." Although the animal continues to take in food, its cells cannot utilise the food and starvation results. We may remark in passing that this generalisation does not apply either to the C-vitamin—*since rats do not suffer in health* if this vitamin is withheld—nor to the A-vitamin, since starvation does not, as a rule, result when this vitamin is withheld. The generalisation was, in fact, established on the basis of the earlier experiments on pigeons and rats before the existence of several vitamins had been recognised and when either the B-vitamin was withheld alone or when a complete absence of vitamins had been established. This in itself weakens the conception of vitamins as substances essential to the life of all cells. But we shall argue here as if this conception applied to the B-vitamin alone. In our preliminary note[5] we *have already criticised this conception.* But it is of such fundamental importance that it may not be out of place to repeat and extend our criticisms.

The evidence on which the conclusion is based is derived entirely from experiments on highly differentiated animals—viz., mammals and birds. If the conclusion is correct it should apply to all forms of life. Numerous attempts *have in fact been made to show that it applies to even the* lowest forms of life: yeasts, bacteria, and plants. The case of yeast is of special interest because it is particularly rich in the water-soluble B-vitamin. It must therefore either be capable of synthetising this vitamin or it must be dependent on a pre-formed supply. The recent work of Nelson, Fulmer, and Cessna[26] has shown quite clearly that yeast is capable of synthetising the water-soluble B-vitamin, and Harden and Zilva[8] have independently arrived at the same conclusion. Since this paper was written Coward and Drummond[2] have published observations which prove that plants can synthetise the fat-soluble A-vitamin, and that apparently this synthesis may be effected from inorganic salts. The experimental evidence on which the claim of the indispensability of vitamins for the lower forms of life was based has been subjected to a critical review and experimental test by Lumière,[18] who showed that these experiments quite clearly established the facts that the *lower forms of life can live and grow in the absence of* vitamins. The addition of material containing vitamins had merely a stimulating effect on the growth of these cells, and it was not even clear whether this effect was due to the addition of the vitamins or to other organic material.

The generalisation that life cannot be maintained in the absence of vitamins, even in its limited form as applying to the B-vitamin, does not necessarily follow from the experimentally established facts. These facts are that a highly differentiated animal—a bird or a mammal—dies in a condition of starvation when the B-vitamin is absent. But although a highly differentiated animal as a whole requires vitamins in order to maintain its life, it does not follow that all the cells of such a highly differentiated animal require the vitamin. If such animals presented a definite lesion in some organ or tissue essential to life, and if such a lesion would account for the condition of emaciation and the eventual death of the animal, then the generalisation that all *cells require vitamins, or even this* particular vitamin, would have to be abandoned. In the past such a lesion has not been found. The functional atrophy of the lymphoid tissue throughout the body had not been noticed and the importance of the function of this tissue in relation to nutrition was not recognised. Starvation was looked upon as the primary effect caused by the absence of B-vitamin, and the atrophy of spleen and thymus which has been repeatedly noticed by several authors was regarded as the result of the chronic starvation.

That the absence of the B-vitamin ultimately leads to a condition of emaciation similar to that produced by the complete absence of food is beyond doubt. To the view that this is due to the failure of the cells of the body to utilise the food absorbed from the intestine in the absence *of the B-vitamin we oppose the conclusion that it is due to* a specific lesion which leads to a functional atrophy of the lymphoid tissue. Such an atrophy of the lymphoid tissue, whether it is brought about by withholding the B-vitamin or by exposure to radiation, or by any other agency such as a toxin, produces a condition of marasmus.

Therapeutic Considerations.

This conclusion suggests the possibility of therapeutic applications apart from the obvious one in conditions of marasmus associated with a lymphopænia. We have seen that an abundant supply of the water-soluble B-vitamin stimulates the functional activity of the lymphoid tissue and increases the number of lymphocytes in the circulating blood. The administration of this vitamin may therefore have a favourable influence in the course of infections in which the defence depends on the activity of the lymphocytes. The old-fashioned administration of yeast to persons suffering from boils is perhaps an empirical application. Conversely it may be possible to inhibit the excessive production of lymphocytes in lymphatic leukæmias by withholding this vitamin. Another more obvious application which would appear to follow is that persons undergoing treatment by X rays or radium, or working with these radiations should receive an ample supply of this vitamin in their diet. We are at present investigating whether the resistance of animals to radium can be increased by an abundant supply of vitamins.

Summary and Conclusions.

Absence of the water-soluble B-vitamin from the diet leads in rats and mice to an atrophy of the lymphoid tissue throughout the body and to a lymphopænia in the circulating blood. The polymorphonuclear leucocytes are not affected. Absence of the fat-soluble A-vitamin does not lead to an atrophy of the lymphoid tissue and there is no lymphopænia.

Absence of the water-soluble B-vitamin leads to characteristic nutritional disturbances such as loss of weight, emaciation, subnormal temperature which may be designated by the term "marasmus." No such marasmus results from withholding the fat-soluble A-vitamin.

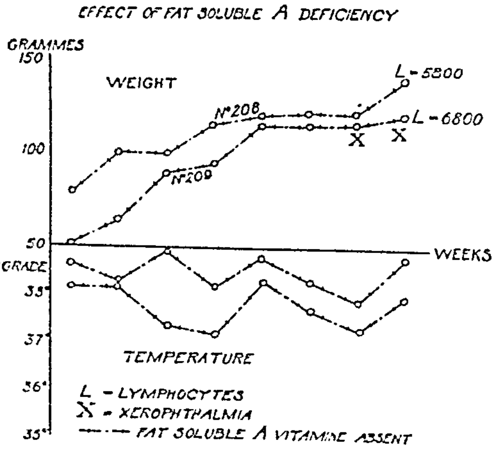
The lymphopænia *established by withholding the* water-soluble B-vitamin is rapidly abolished by the administration of the water-soluble B-vitamin and, *pari passu with it, the concomitant marasmus.* A permanent lymphopænia, and associated with it an atrophy of the lymphoid tissue throughout the body, can also be induced by exposure of rats to sufficient doses of X rays or radium. Such animals then also develop a condition of marasmus similar to that observed when the water-soluble B-vitamin is withheld. Since the functional disturbances in the lymphoid tissue produced by two such widely different agencies lead to the same nutritional disturbances it is concluded that the lymphocytes play a part of fundamental importance in the nutrition of the body. Other evidence points to the conclusion that they are concerned in the absorption and assimilation of food from the intestine.

Further evidence of the existence of an intimate relationship between the *functional activity* of the lymphoid tissue and the general nutrition of the organism is afforded by the fact that an abundant *supply of the water-soluble B-vitamin has a favourable* effect on the development of lymphoid tissue and the number of lymphocytes, and associated with it on the general nutrition of the animal. There is, further, the clinical experience that disturbances of lymphoid tissue are of special significance in infancy and are there frequently associated with nutritional disturbances.

The conception that vitamins—and the B-vitamin in particular—are necessary for the life of every individual cell is criticised. This vitamin is necessary for the maintenance of life of a highly differentiated generally recognised. It is usually attributed to the fact that the deficiency of the fat-soluble A-vitamin takes a longer time to produce its effect. The blood picture in an animal kept on a diet free from the water-soluble B-vitamin, but containing an ample supply of the fat-soluble A-vitamin is, like the general condition of the animal, identical with that just described for the complete absence of vitamins; a great reduction in the number of lymphocytes, especially the small lymphocytes, is found. The polymorphs show no change (Fig. 2, rat 212; Fig. 5, rat 211).

Quite a different condition is presented by an animal kept on a diet free from the fat-soluble A-vitamin, but containing an ample supply of the water-soluble B. In a typical experiment these animals do not show a gradual fall of the temperature, and even in the last stage do not show the profound emaciation of the water-soluble B deficiency (Fig. 4, rats 208 and 209). There is still a fair amount of fat in the body. A characteristic feature is their great susceptibility to infection, of which xerophthalmia is such a frequent instance that it has been regarded by some observers as a specific result of the absence of the fat-soluble vitamin. Other infections, however, may occur while xerophthalmia is absent. These animals do not show an atrophy of the lymphoid tissue (Fig. 1, rats 208 and 209), nor is the total number of lymphocytes in the blood less than that found in normal animals (Fig. 2, rat 208, 209, and 206). Observations on changes on the other elements of the blood are in progress.

FIG. 4.



Curves of weights and of temperatures and number of lymphocytes of two rats kept on a diet free from vitamin A alone, but containing an abundant supply of vitamin B. One of the rats developed xerophthalmia. (Compare with Fig. 3.)

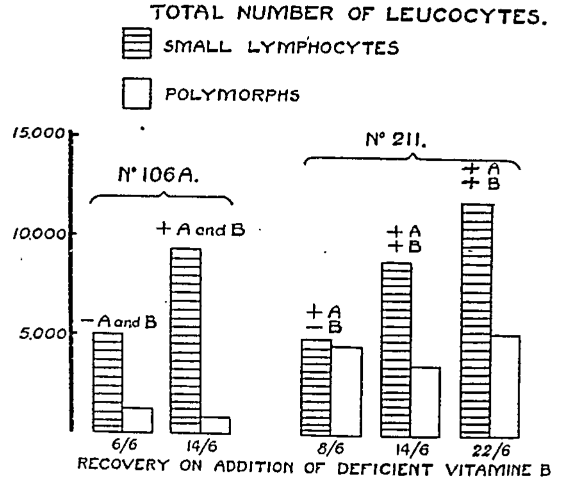
For the purpose of this paper we only refer to the typical condition produced by withholding the A-vitamin alone in order to emphasise that it differs entirely from that produced by the absence of the B-vitamin, both as regards the functional activity of the lymphoid tissue and the general nutritive condition of the animal. The two conditions are contrasted in Table I.:—

TABLE I.

	Lymphoid tissue.	Number of lymphocytes.	Temperature.	State of nutrition.
Absence of—				
Vitamin A ..	Not atrophied	Normal.	Normal.	No emaciation.
Vitamin B ..	Atrophic.	Diminished.	Subnormal.	Emaciation.
Vitamin-A & B	,,	,,	,,	,,

No less striking than the atrophy of the lymphoid tissue, when the water-soluble B-vitamin is withheld, is the recovery of this tissue when this vitamin is added again to the food. Thus in rat 211 (see Fig. 3), which had been kept on the basal vitamin-free ration and cod-liver oil for five weeks, the total number of lymphocytes had fallen to 4800 at a time when the temperature had become very subnormal (35·6°). The weight was then 80 g. The water-soluble B-vitamin was then added in the form of yeast. Within six days the total number of lymphocytes increased to 8800; after another week it had risen further (see Fig. 5) to 11,800. This rise was accompanied by a complete change in the general appearance of the animal, which rapidly increased in weight to 130 g. in two weeks and had a normal temperature. (Fig. 3.)

FIG. 5.



Total number of leucocytes in vitamin deficiency and recovery after the deficient vitamin has been supplied. Rat 106A had been kept on a diet free from both vitamins A and B for seven weeks until 6/6, when both vitamins were added to the diet. Rat 211 (see Fig. 3) had been kept on a diet containing an ample supply of the fat-soluble A, but deficient in water-soluble B for five weeks until 8/6, when the deficient vitamin was added.

In rat 106A (see Fig. 5), which had been kept on a completely vitamin-free basal ration for seven weeks, the total lymphocytes were found to be 5000. Then both vitamins were added and 12 days later the count gave 9900 lymphocytes. There is also a rapid increase in the size of the spleen and thymus, and the Peyer's patches stand out again very prominently. When one considers the extreme degree of atrophy of the thymus in the absence of the B-vitamin, it is astonishing to see the large mass of tissue in an animal which has received the water-soluble vitamin for only a few days (7–10 days). Histologically the various lymphoid tissues show a very active formation of small lymphocytes. Accompanying this change in the lymphoid tissue is the well-known effect on the general nutrition of the animal. It rapidly puts on weight and gets fat, its ordinary adipose tissue getting well loaded with fat.

A Specific Function of the Lymphocyte.

These observations indicate that a specific relationship exists between the water-soluble B-vitamin and lymphoid tissue in the sense that the formation of lymphocytes is impaired in the absence of this vitamin. As a result of our observation the following conception of the mode of action of B-vitamin deficiency has been arrived at: *the lymphocyte has an important and specific function in maintaining the nutrition of the cells of the body, and the disturbances in nutrition which follow the withholding of B-vitamin are secondary to a specific lesion which leads to an interference with the functional activity of the lymphoid tissues.*

This conception will now be considered under the following headings: (*A*) Observations show that an ample supply of vitamins, as compared with a supply restricted but adequate to enable the animals to grow, to breed, and to maintain them in all respects in normal health, has a favourable effect on the functional activity of the lymphoid tissues and on nutrition.

Cowgill[4] utilised these results as a test for the presence of vitamin B in natural food-stuffs. He found that the potency in promoting appetite ran parallel to the potency in relieving symptoms in polyneuritic animals.

Lumière[5,6] fed pigeons with decorticated rice and noticed a marked diminution of intake. There was evidence of stasis in the upper part of the digestive tract. The rice was seen to lie as a compact mass in the stomach. Trituration was defective, and the onward passage of the bolus through the pylorus was greatly delayed. There appeared to be a condition of deficient glandular secretion and hypotonus of the intestinal wall. A small dose of extract of rice polishings provoked abundant glandular secretion and stronger intestinal movements which resulted in rapid *evacuation of the masses of polished rice lying in the upper* intestine. He found that these animals die sooner than starving animals, and quotes Forster, who obtained similar results in dogs.

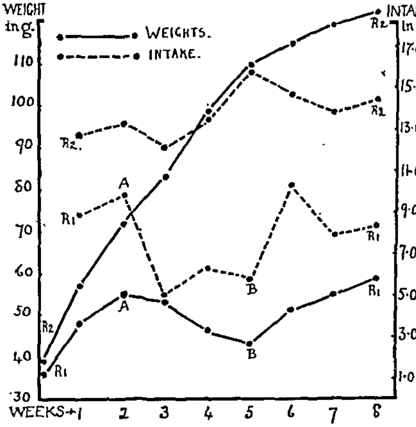


Chart showing weight and intake curves of two rats. R 2: both vitamins administered throughout. R 1: both vitamins administered at first. At A both vitamins were removed; at B a trace of marmite was added to diet. Note sudden falling off of food intake at A and rapid recovery at B.

There appears, therefore, to be a considerable accumulation of evidence that the appetite is adversely affected by the absence of vitamin B from the diet of animals. It is insufficient, however, to state that the vitamin acts by diminishing appetite. Appetite is a general conception, the physical expression of which is the food intake. The problem still remains to explain why the intake is lowered when the vitamin is withheld. It is a general experience that on post-mortem examination of rats fed on diets deficient in vitamins A and B to find the stomach full of food and active fermentation in progress. Sometimes the stomach is definitely dilated. This finding suggests that there is *some defect in the power of the stomach* to deal with its contents and propel them farther down the intestinal canal. *Lumière, too, found the food lying as an inert mass in the stomach* of the pigeons experimented on. From a study of the work detailed, it is suggested that the diminished intake may be accounted for quite simply in the following way. The contractions of the stomach wall are weak, the secretion of the gastric glands is defective, and as a result the stomach is never empty. It is always partly distended with fermenting material. Hunger contractions do not take place, the craving for food becomes low, and the intake falls off considerably. *This theory, that the defect lies in the stomach*, receives valuable support from the fact that the animal responds so very rapidly to the re-addition of the vitamin to the diet. In rats the rise in intake is marked at the end of 24 hours. In pigeons, rapid evacuation of the contents of the intestinal canal occurred immediately after administration of the vitamin. Admitting the fact of lowered food intake, it must be borne in mind, however, that the loss of weight shown by the animals, and their ultimate *death, can still only be partially accounted for.* In Drummond's experiments,[1] improved intake was obtained by adding flavouring agents to the diet; *growth, however, only occurred when the vitamin* was added. In one of Karr's dogs, though the intake remained high in the absence of the vitamin, general symptoms of the vitamin deficiency developed. Forster's experience, that dogs succumbed more rapidly on a vitamin-free diet than when completely deprived of all food, is also very significant.

It may be concluded with some degree of assurance that vitamin B produces its effects by acting primarily, if not solely, on the intestinal canal. In its absence muscle-tone is diminished, peristaltic movements are weak, and there is a reduction in the amount of digestive juice secreted. As a result, stasis occurs, the appetite flags, and the food intake falls off considerably. It is almost certain, however, that the animal is still consuming sufficient to enable it to survive for considerably longer periods than it actually does. *The explanation for the early decline may perhaps be found in the changes which occur to the food which is retained for an abnormally long time in the intestine.* Fermentation soon sets in and toxic bodies may be produced which adversely affect the general health of the animal, death resulting from the combined effects of all the factors mentioned.

Conclusion.

Vitamin B acts by facilitating the efficient carrying out of the functions of the intestinal canal. The main effects produced by the absence of the vitamin—i.e., diminished food consumption, loss of weight, and ultimate death—are due to intestinal stasis and the absorption of toxic bodies which results therefrom.

The expenses of this research have been partly defrayed by a Government grant made through the Royal Society. The prepared palm-kernel oil was kindly presented to me by Messrs. Lever Bros., to whom I tender my thanks.

AORTIC INCOMPETENCE:

A CLINICAL STUDY.

By GEORGE J. LANGLEY, M.D., M.R.C.P. Lond.,
PHYSICIAN, ANCOATS HOSPITAL; ASSISTANT PHYSICIAN, SALFORD ROYAL HOSPITAL, MANCHESTER.

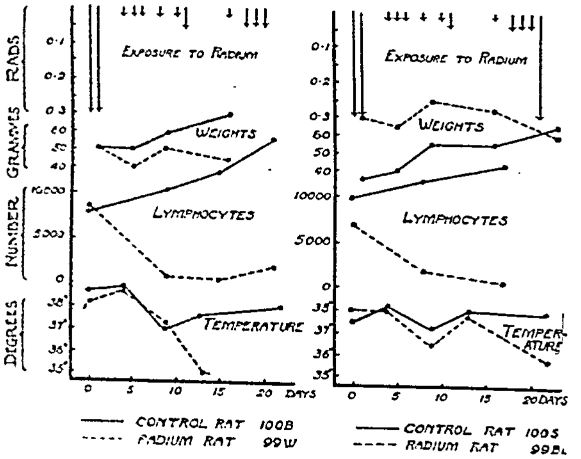
The following analysis of cases of aortic valvular disease was undertaken largely with a view to discovering, if possible, those untoward signs in routine clinical examination which might possibly be utilised to give some warning of the sudden terminal event which so frequently disconcerts the patient's relatives and the physician in charge of the case.

Material and Incidence.

Fifty cases have been taken in the unselected order of their coming under hospital care, and form one section of a series of about 400 heart cases which have been examined. Thus aortic disease would constitute 12½ per cent. of the cardiac cases, a much lower proportion than that found at the Edinburgh Infirmary (Gillespie, Edin. Hosp. Rep., 1898). The lower percentage is no doubt accounted for by the large number of cases sent to a heart clinic nowadays and classified under the heading "effort syndrome." *In no instance in this series was a diagnosis of aortic stenosis made*, the only cases showing a thrill at the base of the heart being such as were shown by X ray to have an aneurysm. The average age of the series was 38 years, the youngest patient being 21 and the oldest 67. Only five cases occurred in women and 40 of the cases were married.

the difference in the length of the arrows giving an approximate indication of the amount of exposure in rads applied on different days. All the four rats exposed to radium reacted in the same way: cessation of growth, fall of temperature, and lymphopænia. When killed the animals showed macroscopically atrophy of the lymphoid tissues; the Peyer's patches were difficult to identify, the thymus had disappeared almost completely, the spleens were very small; in three of the animals the splenic weight was determined and found to be 40 mg., 90 mg., and 110 mg. respectively. Microscopically these tissues were depleted of lymphocytes, and cell division of the plasmoidocytes is infrequent. The figure illustrates the effects of radiation on growth, temperature, and number of lymphocytes with reference to two of the rats, and demonstrates clearly the great similarity to the condition presented by animals in which the lymphoid tissue is undergoing atrophy as the result of withholding the water-soluble vitamin B.

FIG. 7.



Effect of exposure to radium on the body-weight, temperature, and number of lymphocytes. The amount of exposure to radium measured in rads is indicated approximately by the length of the arrows.

C. *Function of Lymphoid Tissue with Relation to Nutrition.*—What is the nature of the function of the lymphoid tissue in relation to nutrition? Unfortunately our knowledge of the function of the lymphoid tissue has hitherto been very obscure in spite of the large amount of work that has been devoted to it. We know very little concerning the condition determining the formation of lymphocytes. The problem of the fate of the lymphocytes is also not yet solved.

From observations on the number of lymphocytes entering the blood stream by the thoracic duct Davis and Carlson[6] conclude that many more lymphocytes enter the blood with the lymph in the course of 24 hours than can be found in the blood at any given time. Bunting and Houston[1] have confirmed this conclusion. They calculate that 3,300,000,000 cells enter the blood stream during 24 hours. Since the number of lymphocytes in the circulating blood remains approximately normal, lymphocytes must either constantly be undergoing disintegration within the body or leave the blood stream. It is probable that both these processes take place. Lymphocytes may temporarily leave the blood stream and return to it by the thoracic duct. Another fraction may leave the body altogether, as Bunting and Houston suggest, by passing through the intestinal mucous membrane into the lumen of the intestine. It is certain from histological evidence that a disintegration of lymphocytes takes place in the lymphoid tissue. But what determines the disintegration of lymphocytes, and what relation there is between disintegration and new formation of lymphocytes, are questions to which no certain answer can as yet be given.

There is evidence that the lymphocytes take a part in the absorption of food from the intestinal canal, where they are present in large numbers in the villi. Fatty substances on account of their specific staining reactions can be shown to be absorbed by lymphocytes.[24] Such histological evidence cannot at present be brought for the nitrogenous constituents of the intestinal contents. But chemical evidence to that effect was furnished by one of us, who showed that during digestion the corpuscular elements of the blood are richer in non-coagulable nitrogen than during sting.[4] This and observations on the absorption of tein introduced parenterally led to the conclusion that the leucocytes take a part in the absorption of the nitrogenous food materials.[3] There are, therefore, two channels by which food material is absorbed and utilised; it is carried partly in solution in the fluids of the blood and partly it is ingested and carried by the cellular elements, presumably the lymphocytes. The passage along the path represented by the lymphocytes is impeded when a lymphopænia has been established either by withholding the water-soluble B-vitamin or by exposure to radiation, and disturbances in nutrition leading to marasmus ensue. There is evidence that the absorption of food is impaired in yet a different manner, when the water-soluble B-vitamin is withheld. Rats kept on the vitamin-free basal ration show, when killed four hours after the food has been given, a stomach distended with food. The intestine is more flaccid and more dilated than in an animal which has received the same ration with the addition of the water-soluble vitamin, and the peristaltic movements are less powerful. The blood-vessels in the pyloric portion of the stomach and in the intestine are not so dilated. This effect on the intestinal tract is an immediate one and occurs at once when the water-soluble vitamin is withheld. The explanation of this apparent general paresis of the intestinal tract requires further investigations. It accounts, perhaps, for the reduced intake of food which, as several observers have noticed, occurs when the water-soluble vitamin is withheld and which so far has received no satisfactory explanation. As shown by the well-filled stomach, the animal does not decline to take food when the water-soluble vitamin is withheld, but the intestinal tract appears to be unable to deal with the food as efficiently as when the vitamin has been given; therefore the capacity to take food is limited. Our attention has been drawn recently to a paper by Lumière,[16] who describes a similar effect in pigeons as the result of feeding on polished rice.

It might be held that the reduced intake of food is in itself an adequate explanation of the condition of marasmus, which is the result of the deficiency of the water-soluble vitamin. This possibility has been considered by Hopkins and later by Drummond,[2] and they are agreed that the reduced food intake is not in itself an adequate explanation of the decline in health which the animals undergo. This view has received confirmation recently by the observations of Karr[14] on dogs. These animals also showed a reduced food intake when the water-soluble vitamin was withheld. But one dog exceptionally maintained its normal food intake. Nevertheless, it, too, passed into the same abnormal condition as the other dogs with a reduced food intake.

Jolly[12] and his collaborators[13] have made an extensive study of the effect of acute and chronic starvation on the lymphoid tissue. They found an atrophy of this tissue, especially of the spleen and thymus, accompanied by a great rarefaction of lymphocytes; in fact, a condition similar to that occurring after radiation and after withholding vitamin B. They also state that chronic underfeeding produces a more intense atrophy than acute starvation. They do not appear to have examined the circulating blood for a lymphopænia. As a result of his observations Jolly[12] looks upon the lymphoid tissue "comme un tissu renfermant des réserves précieuses, d'une grande noblesse au point de vue de la constitution chimique auxquelles l'animal peut faire appel à certains moments. . . . . Le tissu lymphoïde nous apparait ainsi à la fois, comme une réserve de cellules sanguines et comme une réserve de constituants nucléaires." Further observations are necessary to determine whether starvation alone produces as marked a lymphopænia as the withholding of the B-vitamin. In man observations have been made only with reference to the total number of leucocytes, and the effects are apparently not constant. Von Noorden[21] states that in his clinics low numbers—3000 to 4000 total leucocytes—were frequently found in persons emaciated from underfeeding. But he also quoted other observers who have obtained nearly normal figures in such cases. Different results were also obtained on one and the same man, the fasting man Succi; Luciani[15] records a fall from 14,530 to 861 per c.mm. between the first and seventh day. Then they rose to 1530 per c.mm. and remained there throughout his 30 days' fast. In Vienna, however, Tauszk[27] recorded on the same person on another occasion a more gradual diminution from 9600 on the third day to 4200 on the thirtieth and last day of the fast.

Human pathology furnishes further evidence in support of the intimate relation of the lymphoid tissue to nutrition. The blood of infants and young children is particularly rich in lymphocytes, and during the first year gives figures as high as 8000–10,000 per c.mm.[7 11] The lymphocytes then gradually diminish in number, but the level of 2000 per c.mm. which persists throughout adult life is not reached until the sixth year. The fact that disturbances of the adenoid tissue are of special significance in childhood and are frequently associated with disturbances in nutrition[11] is well known. There are, moreover, in infants conditions of marasmus which cannot be ascribed to neglect or deficient

Irregularity occasionally noted in four cases; pulse delay in the radial only noticed twice, but was not particularly looked for. Of the cases not recognised as having a collapsing pulse, all but two had also a presystolic murmur; of these two exceptions, one was found post mortem not to have aortic incompetence, and the other had only a small heart giving rise to no symptoms.

Blood pressure.—Brachial blood-pressure readings (with a Tycos instrument and the auscultatory method) were taken in nearly every case. In eight cases the systolic pressure was 120 mm. Hg or less. In all the rest it was above this normal. The difference between systolic and diastolic pressure was usually extremely well marked, in some cases no diastolic reading being possible. The average difference between systolic and diastolic readings was 85 mm. Hg. No observations were made with regard to arm-leg differences.

Aneurysm.—A definite aortic aneurysm, proven by X ray examination, was found to be present in nine cases, in all of which the W.R. was positive, and the electro-cardiographic left-sided preponderance was very marked indeed.

Lungs.—No lung changes were found in these cases, except the basal crepitations indicating œdema from cardiac failure, and these only in such cases as died in hospital.

Œdema.—The same may be said of œdema generally, and no history of recurrent œdema of ankles was obtained from these patients except in two cases complicated by lesions of other valves and known to be suffering from auricular fibrillation.

Of the three cases which died of slow progressive general anasarca no history of previous cardiac failure was obtainable. One patient, who had advanced renal disease, was said to have occasional variable œdema of the ankles.
